In the case without heat treatment, an orientation-independent single line was observed with a half-width of 205 ± 20 gauss, the g -factor of 2.020 ± 0.005 and a shape of approximately Lorentzian. This results agree with those of Oshima et al.²⁾ and Low.⁵⁾ But in our case, any resolved h.f.s. lines superposed on the broad line could not be observed, which Low observed with weak intensities. The origin of the line width has been discussed by Schneider and Caffyn,¹⁾ and Oshima et al.²⁾

2) Fine structure

With the single crystals quenched from high temperatures (350°C to 785°C) to dry ice temperature, many strongly orientation-dependent lines were observed at room temperature, which were similar to those obtained by Schneider and Caffyn¹⁾. By the following analysis, it will be shown that they correspond to the fine structure of a Mn^{++} ion accompanying a Na^+ ion vacancy in the nearest neighbor site. This fine structure

disappeared in several days and a single broad line appeared, which was just the same as the line observed without heat treatment*. This result agrees with the observation of Schneider and Caffyn.¹⁾

The observed spectra of resonance lines in crystals quenched from about 410°C, are shown in Fig. 1. Fig. 2 shows partially resolved structures superposed on a broad line at sixty eight hours after the quenching.

Now we discuss the results of the above measurements. From the consideration on

the line width and the line shape of the single broad line, Mn^{++} ions are probably in aggregate states prior to the heat treatment, so that line width originating from dipole-dipole interaction is narrowed and h.f.s. are smeared out by the exchange interaction among them, resulting in Lorentzian line shape. This situation has been already discussed by several workers.¹⁾⁻³⁾

According to the experiment of Watkins and Walker⁶⁾, Mn^{++} ions will exist freely in the lattice above 410°C. When the crystal

Fig. 1 (a).

Fig. 1 (b).

* In the first investigation using the powder specimen, partially resolved six h.f.s. lines were observed immediately after quenching, which disappeared in several days and became a single broad line in the same way as in the case of single crystals.¹¹⁾

Fig. 1(c).

Fig. 1 (a), (b), (c). The paramagnetic resonance spectrum of Mn^{++} in quenched NaCl single crystal. The observed spectrum is shown in the lower part of each figure and the calculated one in the upper part. The static magnetic field is along the [100] direction in Fig. 1 (a), the [110] direction in Fig. 1 (b), and the [111] direction in Fig. 1 (c). In Fig. (a), the calculated spectrum, (C), is shown to be composed of two spectra (A) and (B), corresponding to two orientations of Mn^{++} -Na⁺ vacancy complexes in the static magnetic field. In Fig. 1 (b) and (c), a composed spectrum alone is shown. In the observed spectrum, noises and a slight drift of the zero line which eventually occurred are omitted. Noise levels are shown in each figure. The zero point in the field scale indicates the position of the magnetic field corresponding to the g -value of Mn^{++} in NaCl crystal ($g=2.0012$).

Fig. 2. Experimental record for Mn^{++} in quenched NaCl single crystal with H parallel to [100] obtained sixty eight hours later after quenching. Partially resolved structures can be seen. The center strong signal is that due to DPPH. Many marks drawn on the resonance curve are the dc current marks.

is quenched from this temperature, it might be considered that Mn^{++} ions occupying positive ion sites in the lattice are frozen without accompanying Na⁺ vacancies. Then, six h.f.s. lines alone would be expected. However, complex spectra which are composed

of the mixture of fine structure and h.f.s. are always observed instead of six h.f.s. lines alone, even in the case of the crystal quenched from 785°C, at thirty minutes after the quenching. This means that during the process of the quenching or the time to set crystals into cavity, a Na⁺ ion vacancy diffuses through the lattice to form some kind of a complex with a Mn^{++} ion. This supposition may be reasonable by the following discussion. If the diffusion of free Na⁺ ion vacancies is assumed to be isotropic, for simplicity, the time, t , required for a Na⁺ ion vacancy to diffuse on the distance l is estimated by the following relations,

$$t = \frac{\pi}{16D_{vac}} l^2, \quad D_{vac} \cong \frac{\nu a^2}{6},$$

where D_{vac} and ν are the diffusion coefficient and the jump frequency of Na⁺ vacancies and a is the spacing between neighboring Na⁺ ions. The jump frequency ν at room temperature is of the order of 1 c/s.¹²⁾ If the distance l is taken to be about 80Å (the average distance between Mn^{++} ions if they are assumed to distribute uniformly in the NaCl crystal containing Mn^{++} ions of 10^{-4}

mole fraction), the time, t , is estimated to be of the order of several minutes by the above relations*. So during the time of the preparation of our resonance measurement, a Na^+ ion vacancy will certainly diffuse to a site around a Mn^{++} to form a complex. Also it may be considered that during the process of the quenching Na^+ ion vacancies diffuse through the lattice to form some sort of the complexes since the jump frequency of a Na^+ ion vacancy at high temperatures is larger than that at room temperature. Indeed, in NaCl containing small amount of divalent impurities, Ca^{++} , Cd^{++} , Mn^{++} , such complexes are suggested to exist from dielectric loss measurements¹³⁾ and also, in the case of $\text{NaCl}-\text{Cd}^{++}$, from ionic conductivity measurements^{12),14)}. In these cases, it has been suggested that the complex consists of a divalent impurity and a Na^+ ion vacancy occupying one of the Na^+ sites nearest to the divalent impurity. In our case, this position of a Na^+ ion vacancy associated with a Mn^{++} ion is also assumed. Then, the crystalline field at a Mn^{++} ion will no longer be cubic and fine structure will appear in Mn^{++} resonance lines.

Now, there are twelve equivalent positions for the vacancy around a Mn^{++} ion. If the orientation of the vacancy referring to a Mn^{++}

ion is taken as the z -axis, which is assumed to be the $[110]$ direction, for example, as shown in Fig. 3, orthorhombic crystalline field is produced with the x -axis in $[\bar{1}10]$ and the y -axis in cubic axis $[001]$. Then, the effect of the crystalline field on a Mn^{++} ion can be described by the following spin Hamiltonian

$$\mathcal{H}_{\text{crys}} = D[S_z^2 + 1/3 \cdot S(S+1)] + E(S_x^2 - S_y^2). \quad (1)$$

Considering twelve equivalent Na^+ ion vacancy positions, the z -axis must be taken as one of the six equivalent $[110]$ orientations with appropriate choices of the x - and y -axes.

With Zeeman energy and the hyperfine interaction with ^{55}Mn nucleus, the total spin Hamiltonian of a Mn^{++} ion is given by

$$\mathcal{H} = g\beta\mathbf{H} \cdot \mathbf{S} + \mathcal{H}_{\text{crys}} + \mathbf{A} \cdot \mathbf{I} \cdot \mathbf{S}, \quad (2)$$

where the first term gives Zeeman energy and the last term represents the hyperfine interaction. Here fourth order terms in components of $\mathbf{S}$ and the anisotropic part of the hyperfine interaction are omitted because experimental data can be explained without them.

Let the magnetic field H be in the (θ, φ) direction in the (x, y, z) -coordinate system. In the second order perturbation calculation, the field strength of resonance lines for the electronic ($M \leftrightarrow M+1$) transition is given by

$$\begin{aligned} H = H_0 - \frac{2M+1}{2} [D(3\cos^2\theta - 1) + 3E\cos 2\varphi \cdot \sin^2\theta] \\ - \frac{1}{2H_0} [(D - E\cos 2\varphi)^2 \cdot \sin^2\theta \cdot \cos^2\theta + E^2 \sin^2\theta \cdot \sin^2 2\varphi] [24M(M+1) - 4S(S+1) + 9] \\ - \frac{1}{8H_0} \{ [D\sin^2\theta + E\cos 2\varphi(1 + \cos^2\theta)]^2 + 4E^2 \cos^2\theta \cdot \sin^2 2\varphi \} \cdot [2S(S+1) - 6M(M+1) - 3] \\ - Am - \frac{A^2}{2H_0} [I(I+1) - m^2 + m(2M+1)], \end{aligned} \quad (3)$$

where M and m are the components of the electronic and nuclear spins in the applied magnetic field, H_0 is $h\nu/g\beta$ and the values of D , E , and A are reduced by a factor of $g\beta$ from those in Eq. (2).

In the present case, resonance spectrum

* According to Haven (Report of Bristol Conference in the reference (13)), the jump frequency of free Na^+ vacancies at 20°C in the NaCl crystal is estimated to be 17 c/s. If this value is used, it takes about 28 sec for Na^+ vacancies to diffuse on the same distance.

consists, in general, of 180 lines because the z -axis of the crystalline field must be taken as each one of the six orientations and the fine structure consists of 30 lines for each direction of the z -axis. But, if the magnetic field H lies along some symmetry axis, the number of resonance lines is reduced. For example, if H is parallel to the cubic axis, resonance lines consist of two sets, one being given by Eq. (3) with $\theta=45^\circ$, $\varphi=0^\circ$ and the other with $\theta=90^\circ$, $\varphi=90^\circ$ (See Fig. 1 (a)). Similarly, for the cases in which H lies in

[110] and [111] the numbers of the equivalent sets can be easily obtained. Table I shows the equivalent values of θ and φ for these sets, together with the numbers of the equivalent orientations of z -axes for each set.

Fig. 3. A coordinate system with the origin at the position of Mn^{++} on a Na^+ site. The crystalline field about a Mn^{++} ion accompanying a Na^+ vacancy at one of the nearest neighbor Na^+ sites has orthorhombic symmetry, and for the analysis of the fine structures, x , y , z -axes were taken as shown in this figure (see text).

Table I. Classification of the orientations of equivalent crystalline field z -axes at Mn^{++} in the static magnetic field.

Direction of H	θ	φ	Abundance
[100]	45°	0°	4
	90°	90°	2
[110]	0°		1
	90°	0°	1
	60°	$\frac{1}{2} \cos^{-1} \left(-\frac{1}{3} \right)$	4
[111]	$\cos^{-1} \sqrt{\frac{2}{3}}$	90°	3
	90°	$\frac{1}{2} \cos^{-1} \left(\frac{1}{3} \right)$	3

By fitting the observed spectra for the orientations of H in [100] and [110] with the calculated ones as shown in Fig. 1 (a), (b), we find the following values for the parameters, g , A , D , and E .

$$\begin{aligned} g &= 2.0012 \pm 0.0008 \\ A &= -88.8 \pm 0.8 \text{ gauss} \\ D &= 137.9 \pm 1 \text{ gauss} \\ E &= 51.4 \pm 0.4 \text{ gauss} \end{aligned} \quad (4)$$

The signs of D and E in the above assignments were determined from the considera-

tion of the variation of the spacings of h.f.s. multiplets assuming that A is negative.

We now compare the experimental results for H parallel to [111] with the spectrum calculated by Eq. (3) using the parameters given by Eq. (4). As shown in Fig. 1 (c), the agreement of the observed spectrum with the calculated one is not satisfactory. This may partially be due to the difficulty of setting the crystal with the desired orientation because the crystal used was cut along a (110) plane. Moreover, in the observed spectrum, some of the lines expected at the lowest field side are so weak that their existence can not be confirmed by the masking effect of noise. Theoretically, it is expected that these lines have equal intensities with those of the corresponding lines at the highest field side. We have no appropriate interpretation as to this intensity anomaly even if a slight distribution of the orientation of the crystal axes due to cracks is taken into consideration. Wertz and Auzins¹⁵⁾ also reported similar anomaly in intensity in the case of Cr^{+++} resonance in $MgO-Cr^{+++}$ crystal.

The width of h.f.s. components at the highest and lowest field sides in the spectra with H parallel to [100] and [110] is 10 ~ 12 gauss, and the width between maximum slopes of the main h.f.s. components ($M=1/2 \leftrightarrow -1/2$ transition) observed with H parallel to [100] is about 8 gauss. The origin of these widths may be attributed mainly to the unresolved h.f.s. due to neighboring six Cl nuclei and a small distribution in the parameters D and E due to strains in the crystal. Also the dipolar interactions with neighboring Cl nuclei and Na nuclei contribute to the width by 2.7 gauss for H parallel to [100] and by 2.2 gauss for H parallel to [110].

Watkins and Walker observed complex structures when the crystal was heated to 200°C. By analyzing them, they concluded that two types of $Mn^{++}-Na^+$ vacancy complexes existed in the crystal, one with the vacancy in the nearest neighbor position with respect to a Mn^{++} ion and the other in the next nearest neighbor position, and they obtained the values of the parameters for each case. In order to compare the value of of the parameters which they obtained for the former case with our values given by Eq. (4), a new coordinate system is taken,

in which the z -axis is along the cubic axis and the x -axis in the direction of Mn^{++} to Na^+ vacancy. In this new coordinate system the following values of the parameters are obtained:

$$D = -146.0 \pm 1 \text{ gauss},$$

$$E = 43.3 \pm 0.3 \text{ gauss}.$$

These values agree very well with those obtained by Watkins⁷⁾.

In our measurements, the fine structure of the resonance lines of Mn^{++} ions which accompany Na^+ ion vacancies occupying the next nearest neighbor Na^+ sites could not be observed. This indicates that the complex with the vacancy in the nearest neighbor Na^+ site is more stable than that with the vacancy in the next nearest neighbor Na^+ site, so that the former prevails at room temperature when the specimens were quenched from high temperature. According to Watkins⁷⁾, the binding energy of the former type of complex is larger than that of the latter by 0.03 eV. This difference in the binding energy may be the reason why the resonance lines of one type of complexes could not be observed in our measurement.

The change of the relative intensity of the resonance line with time after quenching was

Fig. 4. The change of the intensity of the lowest h.f.s. line ($m = -5/2$) in $M = 1/2 \leftrightarrow -1/2$ transition when the static magnetic field is parallel to [100] in NaCl single crystal quenched from 410°C. Two decay curves correspond to the cases of two different times of the duration of heating at 410°C, which is about forty minutes for the lower curve, (i), and is about three hours for the upper curve, (ii). For each case the intensity of the resonance line was compared with the intensity of the resonance line of DPPH. The relative intensities are so normalized that they have the same value at the starting time of the measurement which is an hour and a half after the quenching.

investigated with the lowest h.f.s. line in $M = 1/2 \leftrightarrow -1/2$ transition when H is parallel to [100], using the specimen quenched from 410°C. The results are shown in Fig. 4. These two decay curves correspond to two different times of the duration of heating at 410°C which are about forty minutes and about three hours respectively. The reason for the disappearance of the fine structure of the resonance line will be that the Mn^{++} — Na^+ vacancy complexes diffuse through the lattice and eventually form aggregates of Mn^{++} ions. As already stated, Mn^{++} ions in aggregate state in the crystal should not yield fine structure of the resonance lines, but they should yield a single broad line.^{15, 16} Fig. 4 shows that in the case of the forty minutes' heating the initial decrease of the intensity of the resonance line is rapid. This may be explained as follows: As the time of heating is not long enough to separate Mn^{++} ions completely, the initial recovery of the aggregate state of Mn^{++} ions is attained quickly. In the case of three hours' heating the decay is slow, meaning that the Mn^{++} — Na^+ vacancy complexes are distributed more uniformly throughout the lattice, so that it takes a longer time to diffuse and aggregate together. It may be considered that aggregation of Mn^{++} ions may occur at a sort of internal boundary or may form an ordered state with Na^+ ion vacancies as found in the NaCl— Ca^{++} crystal by Miyake and Suzuki¹⁶⁾. Then, when the crystal is heated, Mn^{++} — Na^+ complexes may first diffuse easily on this boundary plane, and after a prolonged heating, they may diffuse slowly to the inside of the host crystal itself. After quenching, Mn^{++} — Na^+ complexes may diffuse back to the aggregate state just in the reversed way, and this might be the origin of the different rate of the intensity decay for the both cases in Fig. 4.

It seems to us that the quantitative analysis of the decay curve might supply some valuable informations about the divalent impurity diffusion. Though a quantitative treatment of the decay curve on the base of the theory of the impurity diffusion by vacancy mechanism¹⁷⁾ has been tried, any conclusive explanation could not be obtained at the present stage because no reliable information about the aggregate state of Mn^{++}

ions is available.*

§ 4. Concluding Remarks

In this paper there have been presented the experimental results of the resonance spectrum of Mn^{++} contained as impurity ions in NaCl crystals, and the fine structure of the resonance lines observed in the crystals quenched from high temperature has been analyzed on the base of a spin Hamiltonian containing an orthorhombic crystalline field term. From the analysis of the fine structure the existence of Mn^{++} - Na^+ vacancy pairs, "complexes", was confirmed. At room temperature these free complexes are unstable and diffuse slowly through the lattice to form aggregates of Mn^{++} ions.

The authors wish to thank Dr. T. Kojima for his valuable suggestions about the complex formation from Mn^{++} and positive ion vacancies. One of the authors (J.I.) would like to thank Dr. G. D. Watkins for his valuable discussions which were given to him at Duke University on the occasion of the Conference on the Radio and Microwave Spectroscopy, November 1957.

* In order to obtain some informations about the aggregate state of Mn^{++} ions, we made some observation on the NaCl- Mn^{++} single crystal used in the resonance experiments by means of a electron microscope. Because of ambiguity in etching, we could not obtain any reliable information about this problem by the electron microscope studies.

Nuclear Magnetic Resonance Studies of Iodine Ions in Aqueous Solution

By Junkichi ITOH and Yukio YAMAGATA

Department of Physics, Osaka, University, Osaka, Japan

(Received June 19, 1958)

Chemical shift and line width were measured for the nuclear magnetic resonance of iodine nuclei in aqueous solutions of alkali iodides. The chemical shift was independent of temperature, but was dependent on the concentration of the solution. The spin lattice relaxation time calculated from the line width varied with temperature as well as concentration. General trend of the variation of the spin lattice relaxation time agrees with that of viscosity. By analysing the data of the chemical shift and spin lattice relaxation time, it is suggested that even in very dilute solution there exists chemical shift of the order of 6×10^{-4} as compared to the case of 'pure ion'.

§ 1. Introduction

When strong electrolytes such as alkali halides are desolved in water, each molecule separates into positive and negative ions. Often the nuclear magnetic resonance frequency for these ions was taken as a standard, to express the chemical shift for other compounds containing the same nucleus. To discuss the chemical shifts in solid metal halides, it is necessary to know the shift of resonance frequency for solids from that of pure ion¹⁾, and in some previous works, the shift of resonance frequency of the solids from that of ions in aqueous solution was taken as the true shift from 'pure ion', without detailed considerations^{2), 3)}. However, ions in aqueous solution are usually surrounded by several water molecules of hydration⁴⁾ and, as pointed out already by Saika and Slichter⁵⁾, there seems to exist considerable effect on resonance frequency by the hydration. Moreover, in the case of Tl nuclei, Gutowsky and McGarvey⁶⁾ observed that the resonance frequency for Tl ions in aqueous solution showed marked concentration dependency in some cases. Also, they pointed out that a similar concentration dependence of the resonance frequency was found in the case of Cs ions, suggesting some other effects than the hydration.

During the investigation of the chemical shifts for solid alkali halides, which will be published in near future, we noticed that it is necessary to know the true resonance frequency for nuclei in pure alkali or halogen ions. However, it is very difficult, almost

impossible, to measure the resonance frequency for pure ions, so we aimed to investigate the effect of hydration for ions in aqueous solution. If the hydration has some effect on the chemical shift, it seems probable that also it has some effect on the electric quadrupole interaction, when the nucleus has spin larger than 1 and momentary configuration of water molecules of hydration is not highly symmetrical, and by this electric quadrupole interaction spin lattice relaxation time, T_1 , of the nucleus in ion may be considerably shortened. Therefore, we measured the concentration and temperature dependence of the shift and spin lattice relaxation time for various metal and halogen ions in aqueous solution. In this report, we shall describe the results of our experiments on iodine ions. As will be discussed in section III, it is very difficult to analyse clearly our experimental results to obtain the resonance frequency for 'pure ion', though it may be suggested that there exists considerable chemical shift for iodine ion even in very dilute solution as compared to 'pure iodine ion', and further experiments of different kinds should be made to determine accurately true resonance frequency for 'pure ion'.

§ 2. Experimental Results

(a) The chemical shift.

The resonance field for iodine ions in aqueous solution was compared with that for solid sodium iodide. First, we desolved potassium iodide in water and noticed that there existed

considerable concentration dependency of the resonance field. Since the spin lattice relaxation time of iodine nuclei is rather short in aqueous solution which will be described in (b), it might be the case that the shift in resonance field is not a true chemical shift, but is caused by some other origins such as second order quadrupole effect⁷⁾. If the shift is a true chemical shift, $\Delta H/H$ where ΔH is the shift of the resonance field from a standard (in this case the resonance field for solid sodium iodide) and H is the applied field, will be constant for all values of H ⁸⁾, while if the shift originated from quadrupole effect, $\Delta H/H$ will depend strongly upon H . We checked that the resonance field for the standard solid sodium iodide was exactly proportional to the frequency, by measuring the ratio of the resonance frequency for sodium ions in aqueous solution of sodium bromide and that for iodine nuclei in solid sodium iodide at various fields. In the case of sodium nuclei in aqueous solution, the line width is very narrow, being almost equal to the width corresponding to field inhomogeneity, and no effect of second

order quadrupole term will exist.

The measured values of $\Delta H/H$ are constant within experimental errors at three frequencies, 3.4, 4.5 and 6.0 Mc/sec, indicating that there exists a true chemical shift between the resonance field for iodine ions in aqueous solution and that in solid sodium iodide. The results of the measurements are shown in Fig. 1, in which the relative shifts of the resonance field for aqueous solution from that for solid sodium iodide are plotted against the concentration of the solution. The resonance for solution lies always in diamagnetic side with respect to that for solid. In this figure, the results of the measurements for other alkali iodides, NaI and LiI, are also included. The concentration dependence of the shift is almost linear, and the shift is independent of the nature of positive ions.

Next, we measured the temperature dependence of the chemical shift. In this case, we used only an aqueous solution of potassium iodide with the concentration of 1 gr of KI in 1 gr of water. Keeping the reference sample of solid sodium iodide at room temperature, the temperature of the solution was changed from room temperature upto about 80°C. No

Fig. 1. Concentration dependence of the chemical shift for iodine ions in aqueous solutions. $\Delta\sigma$ is relative shift of the resonance for aqueous solutions from that for solid sodium iodide. Different marks show the experimental results for KI aq., NaI aq. and LiI aq. at three frequencies: $\circ$ KI aq. at 3.4 Mc/sec, $\odot$ KI aq. at 4.5 Mc/sec, $\otimes$ KI aq. at 6.0 Md/sec, $\square$ NaI aq. at 3.4 Mc/sec, and $\triangle$ LiI aq. at 6.0 Mc/sec. Solid line was drawn to fit best with the experimental plots.

Fig. 2. Concentration dependence of the inverse of T_2 for aqueous solutions of potassium iodide and sodium iodide. Circular marks are the experimental points for KI aq., while square marks are those for NaI aq.. Solid curves show the concentration dependence of η , normalized to fit best with the experimental plots of $1/T_2$ for KI aq.

change in $\Delta H/H$ was observed within the experimental errors which were about $\pm 0.5 \times 10^{-5}$.

(b) *The width of the resonance line; The spin lattice relaxation time.*

Since the nuclear magnetic resonance line width is rather broad for iodine ions in aqueous solution and also the line shape is Lorentzian, it will be safe to assume that $T_1 = T_2$ in this case. Therefore, to determine the value of T_1 , we only measured the line width, δH , (full width between maximum and minimum deflections in the derivative of the absorption curve), and $T_1 (= T_2)$ is calculated by the relation $T_1 = 2/\sqrt{3} \gamma \delta H$.

Fig. 3. Temperature variation of the inverse of T_2 for aqueous solutions of potassium, sodium and lithium iodides, with various concentrations. 1: $\circ$ KI aq. 1.10 mole/liter of water, 2: $\circ$ KI aq. 0.27 mole/liter, 3: $\bullet$ KI aq. 7.5 mole/liter, 4: $\blacksquare$ NaI aq. 1.21 mole/liter, 5: $\square$ NaI aq. 0.30 mole/liter, 6: $\blacksquare$ NaI aq. 8.3 mole/liter, 7: $\triangle$ LiI aq. 1.30 mole/liter. Solid curves show the temperature dependence of the values of η/T for corresponding concentrations, normalized to fit best with the experimental plots of $1/T_2$ for KI aq. with the concentration of 1.10 mole/liter of water.

δH was measured for aqueous solutions of potassium, sodium and lithium iodides with various concentrations and at different temperatures. Typical values of $1/T_1$ calculated from the line width are shown in Fig. 2 and Fig. 3. T_1 depends upon the concentration in the case of NaI aq., while T_1 is almost constant in the case of KI aq. The viscosity of the solution of sodium and potassium iodides changes with the concentration by similar ways as those of $1/T_1$. Also for the temperature

dependency of $1/T_1$, similar parallelity with the change of viscosity exists. The absolute values of T_1 are much shorter than those expected from the dipolar interaction with surrounding water molecules which is time dependent by the Brownian motion of water molecules. Therefore it is suggested that the origin of the relaxation is time varying electric quadrupole interaction which is produced by the motion of water molecules of hydration.

The extrapolated value of T_1 for infinitely dilute solution which is, of course, equal for KI aq. and NaI aq., is rather short even at higher temperatures.

§ 3. Discussion

Though the concentration of the solution by which nuclear magnetic resonance measurement of iodine nuclei is possible is not so dilute as is considered 'dilute in electrochemical sense', the interaction between positive and negative ions may be neglected in the discussion of nuclear magnetic relaxation for dilute solutions used in our experiment, because the width of the resonance line is almost independent of the concentration when the concentration of the solution is made less than 3 mole/liter for KI aq. and less than 2 mole/liter for NaI aq.. This means that in these cases the spin lattice relaxation time is determined solely by the interaction between the ion and water molecules of hydration. If, as a first order approximation, we neglect the interaction between ions at all concentrations, $1/T_1$ may be assumed to be proportional to η/T according to the theory of Bloembergen, Purcell and Pound⁹, where η is the viscosity of the solution and T is the temperature. In Fig. 2 and Fig. 3, values of η/T^{10} are also shown, normalizing the curves of η/T to fit best with the experimental $1/T_1$ -curve for dilute solution of KI. General tendencies of the curves of $1/T_1$ and η/T agree with each other, suggesting that the main origin of the relaxation is time dependent electric quadrupole interaction of iodine nuclei which is produced by the water molecules of hydration. It is not clear, however, whether the electric quadrupole energy is produced by the asymmetric configuration of water molecules around the iodine ion which is made time dependent by the rotational motion of the system of iodine ion plus water molecules of hydration among

free water, or the configuration of the water molecules of hydration changes from time to time by Brownian motion, or both.

Next, we shall discuss the chemical shift. The chemical shift shows considerable concentration dependency. Therefore, contrary to the discussion given above, some effect from positive ions should exist. The fact that the shift is independent of the kind of positive ions suggests that the perturbing effect of positive ions is not the association to form neutral molecule. On the other hand, according to the theory of strong electrolyte¹¹⁾, a sheath of positive charge is formed around each negative ion on an average, the mean radius of which is determined by the concentration, and this positive sheath may polarize the water molecules of hydration around the negative ion. This polarization, in turn, may perturb the charge distribution of the negative ion and change the chemical shift.

If this picture is the actual case, there must exist concentration dependence of momentary electric quadrupole energy which is the origin of the spin lattice relaxation. In fact, strictly speaking, the measured values of $1/T_1$ are not exactly proportional to η/T .

Now, we shall assume that root mean square of momentary electric quadrupole energy and the shift come from the same origin. Then, $\bar{E}_Q$, root mean square of quadrupole energy, can be assumed to be proportional to $(1/T_1\eta)^{1/2}$, and also to the net shift, σ , from purely ionic state. Then the following relation is easily derived:

$$\frac{(1/T_1\eta)_1^{1/2} - (1/T_1\eta)_0^{1/2}}{(1/T_1\eta)_0^{1/2}} = \frac{\sigma_1 - \sigma_0}{\sigma_0} \quad (1)$$

where 1 and 0 means two solutions of concentration 1 and 0, provided that all these quantities are measured at one temperature. Taking the concentration 0 as very dilute one (or the extrapolated one to zero concentration), σ_0 , that is the chemical shift of iodine nuclei in very dilute solution as compared to that of 'pure ion', can be calculated. The estimated value of σ_0 from the experimental values of $(1/T_1)_1$, $(1/T_1)_0$, and $\sigma_1 - \sigma_0$, is $\sim 6 \times 10^{-4}$, both for aqueous solutions of potassium and sodium iodides. Of course, equation (1) might be very crude one, since the origin of σ and $1/T_1$ is not known exactly. So, the estimated value

of σ_0 might be only tentative, but, to explain the concentration dependence of the shift and also rather short relaxation time in very dilute solution, we must assume considerable chemical shift from 'pure ion' even at very small concentration.

The main force between an ion and surrounding water molecules of hydration is probably electrostatic one, but there might exist some kind of bonding by which small part of electron charge of the ion may transfer to water molecules. Then by p-electron hole produced by electron transfer, chemical shift and also electric quadrupole interaction for iodine nuclei will be produced. In this case, theoretical treatment given by Saika and Slichter⁴⁾ or Yoshida and Moriya¹⁾ will be applicable. If we assume the number of water molecules attached to one iodine ion is four, the estimated fraction of p-electron hole per one pair of iodine ion and water molecule becomes about 4 percent to interpret the chemical shift in very dilute solution from that for 'pure ion'. Then electric quadrupole energy of about 80 Mc/sec is expected for a pair of iodine ion and water molecule. If we assume further that electric quadrupole interaction of this order of magnitude fluctuates with time by a correlation time corresponding to the viscosity of the solution, we get spin lattice relaxation time of right order of magnitude as compared with the experimental values. Concentration dependency of the chemical shift can be well interpreted by the change of electron transfer caused by the polarization effect due to positive ions around the hydrated iodine ion. The analysis of the experimental data given above has been done, taking these considerations on the chemical shift and spin lattice relaxation in mind.

Interactions between ions and water molecules of hydration can also be investigated by measurements of the chemical shift and spin lattice relaxation time of proton. Broersma¹²⁾ and Shoolery and Alder¹³⁾ investigated proton magnetic resonance, but direct correlation between proton and metal or halogen nuclear magnetic resonances was not clearly shown in the present stage.

Hitherto, the chemical shift in metal halides was referred to that of ions in aqueous solution, and also often the nuclear magnetic moments have been calculated from the reso-

nance condition for ions in aqueous solution with diamagnetic shielding correction for 'pure ion'^(13,14). Therefore, these values should be considerably revised by the chemical shifts of the ions in aqueous solution as compared to the pure ion.

Similar concentration dependency of the shift was observed in other alkali metal and halogen ions, too. The results of these measurements for other ions will be reported in near future.

The Lower Excited States and the Phosphorescent State of Diphenyl II. Scheme of Modification of MO

Kaoru IGUCHI

Electrical Communication Laboratory, Musashino-shi, Tokyo

(Received June 24, 1958)

To treat the problem of phosphorescence of alternant hydrocarbon we propose a new method to take account of the mixing of higher order AO's.

We give here a theoretical scheme of the modification of $2p\pi$ MO with the addition of $3d$ AO's for diphenyl molecule. With the modified MO's thus obtained, the singlet triplet intercombination matrix is given in the concrete form.

§ 1. MO Expansion

The $2p\pi$ MO method with two center integrals is unable to approximate the observed value of the singlet-triplet intercombination intensity in the phosphorescence of alternant hydrocarbon. Some authors have yet published works concerning this problem.¹⁻³

But, in the preceeding paper⁴⁾ we have proposed a new method modifying MO's consisted simply of $2p\pi$ AO's with higher order AO's.

A generalized MO ϕ^s can be written in the following form;

$$\phi^s = \sum_A \sum_{pqr} c_A^{pqr} x_a^p y_a^q z_a^r e^{-\delta_A r_a}. \quad (1)$$

Note. A. atom. x_a, y_a, z_a . coordinates measured from the atom A. δ_A depends on (pqr) . $r_a^2 = x_a^2 + y_a^2 + z_a^2$.

When the antisymmetric property of MO by the reflection to the xy plane is taken into account, the Eq. (1) can be transformed as;

$$\phi^s = \sum_A \{c_A^0 \chi_A + (c_A^1 x_a + c_A^2 y_a) \chi_A' + \dots\} = \sum_i \alpha_i' S_i + \beta_i' U_i + \gamma_i' V_i + \dots \quad (2)$$

Here S_i , U_i , and V_i are the simple symmetry MO's defined for an irreducible representation Γ as follows;

$$\left. \begin{aligned} S_i &= \sum_A \sigma_A^i(\Gamma') \chi_A, & \Gamma' &= \Gamma \times B_{1u} \\ U_i &= \sum_A \sigma_A^i(\Gamma'') \sqrt{\frac{2\delta'^2}{3}} x_a \chi_A' = \sum_A \sigma_A^i(\Gamma'') \xi_A, & \Gamma'' &= \Gamma \times B_{2g} \\ V_i &= \sum_A \sigma_A^i(\Gamma''') \sqrt{\frac{2\delta'^2}{3}} y_a \chi_A' = \sum_A \sigma_A^i(\Gamma''') \eta_A, & \Gamma''' &= \Gamma \times B_{3g} \\ \chi_A &= \sqrt{\frac{\delta^6}{\pi}} e^{-\delta' r_a} z_a \dots 2p\pi \text{ AO}, & \xi_A &= \sqrt{\frac{2\delta'^7}{3\pi}} e^{-\delta' r_a} x_a z_a \dots 3d_{xz} \text{ AO}. \\ \eta_A &= \sqrt{\frac{2\delta'^7}{3\pi}} e^{-\delta' r_a} y_a z_a \dots 3d_{yz} \text{ AO}. \end{aligned} \right\} \quad (3)$$

$\sigma_A^i(\Gamma')$ is already known in the construction of $2p\pi$ symmetry MO, and from this we can easily find out $\sigma_A^i(\Gamma'')$ and $\sigma_A^i(\Gamma''')$.

On the other hand, the Hueckel orbitals are found in the form;

$$\left. \begin{aligned} 2p\pi \text{ MO } \phi_f &= \sum_i \alpha_{fi} S_i = \sum_A \alpha_A^f \chi_A, & f &= 1 \rightarrow n \text{ occupied}, n' \rightarrow 1'(n+1) \rightarrow 2n) \text{ unoccupied} \\ 3d_{xz} \text{ MO } \psi_f &= \sum_i \beta_{fi} U_i = \sum_A \beta_A^f \xi_A, & f &= 1 \rightarrow 1' \\ 3d_{yz} \text{ MO } \omega_f &= \sum_i \gamma_{fi} V_i = \sum_A \gamma_A^f \eta_A. & f &= 1 \rightarrow 1' \end{aligned} \right\} \quad (4)$$

Here α_A^f , β_A^f , γ_A^f are the Hueckel coefficients.⁵⁾

One might consider the necessity to include $3p\pi$ MO's in the Eq. (2) because they lie lower than $3d$ MO's. But even if they were included, it can be shown that they disappear in the course of evaluation of S - T intercombination integral because of the symmetry property.

§ 2. Determination of Expansion Coefficients

Substituting Eq. (4) into Eq. (2) we have the following form for the modified MO's;

$$\left. \begin{aligned} \phi_i^s &= \phi_i + \sum_k a_{ik} \phi_k + \sum_f b_{if} \psi_f + \sum_f c_{if} \omega_f, & \phi_k^s &= \phi_k - \sum_i a_{ik} \phi_i + \sum_f b_{kf} \psi_f + \sum_f c_{kf} \omega_f, \\ \psi_j^s &= \psi_j - \sum_i b_{ij} \phi_i - \sum_k b_{kj} \phi_k, & \omega_f^s &= \omega_f - \sum_i c_{if} \phi_i - \sum_k c_{kf} \phi_k. \end{aligned} \right\} \quad (5)$$

$i, j = 1 \rightarrow n \text{ occupied. } k, l = n' \rightarrow 1' \text{ unoccupied. } f, g = 1 \rightarrow 1'.$

With these MO's, the orthonormality can be proved to hold if one retains until the first order terms.⁶⁾

The energy diagonalization conditions also can be shown to be satisfied by the following choice of the coefficients a_{ik} , b_{if} , c_{if} etc.;

$$\left. \begin{aligned} a_{ik} &= \frac{(\phi_k H' \phi_i)}{E_i - E_k}, & b_{if} &= \frac{(\psi_f H' \phi_i)}{E_i - E_{\psi_f}}, & c_{if} &= \frac{(\omega_f H' \phi_i)}{E_i - E_{\omega_f}}, \end{aligned} \right\} \quad (6)$$

$H' = G^s - G = \sum_j 2(J_j^s - J_j) - (K_j^s - K_j),$

and E_i = energy of ϕ_i etc.

J_j and K_j are Coulomb and exchange operators respectively. Here the Hueckel MO ϕ_i 's

are assumed to be sufficiently approximate to SCF orbitals.

When expanded in MO integrals.

$$\begin{aligned}
 (\varphi H' \phi_i) &= (\varphi | \sum_j 2(J_j^s - J_j) - (K_j^s - K_j) | \phi_i) \\
 &= \sum_{kj} 4a_{jk} [\varphi \phi_i | \phi_j \phi_k] + \sum_{jj} 4b_{jj} [\varphi \phi_i | \phi_j \phi_j] + \sum_{jj} 4c_{jj} [\varphi \phi_i | \phi_j \omega_j] \\
 &\quad - \sum_{kj} a_{jk} \{ [\varphi \phi_k | \phi_i \phi_j] + [\varphi \phi_j | \phi_i \phi_k] \} - \sum_{jj} b_{jj} \{ [\varphi \phi_j | \phi_i \phi_j] + [\varphi \phi_j | \phi_i \phi_j] \} \\
 &\quad - \sum_{jj} c_{jj} \{ [\varphi \omega_j | \phi_i \phi_j] + [\varphi \phi_j | \phi_i \omega_j] \},
 \end{aligned} \tag{7}$$

φ = either of ϕ_i , ψ_σ , ω_σ .

$$i, j = 1 \rightarrow n. \quad k, l = n' \rightarrow 1' \quad (n+1 \rightarrow 2n). \quad f, g = 1 \rightarrow 1' \quad (1 \rightarrow 2n).$$

These MO integrals can be expanded in terms of AO integrals as follows;

$$\begin{aligned}
 [\phi_i \phi_j | \varphi \varphi'] &= \sum_{ABCD} a_A^i a_B^j \varepsilon_C \varepsilon_{D'} (\chi_A \chi_B | \zeta_C \zeta_{D'}) \\
 &\cong \sum_{AO} a_A^i a_A^j \varepsilon_O \varepsilon_{O'} (\chi_A \chi_A | \zeta_O \zeta_{O'}) \quad \text{in Pariser approximation} \\
 [\phi_i \varphi | \phi_j \varphi'] &= \sum_{ABCD} a_A^i \varepsilon_B a_C \varepsilon_{D'} (\chi_A \zeta_B | \chi_C \zeta_{D'}) \cong \sum_{AO} a_A^i \varepsilon_A a_C \varepsilon_{O'} (\chi_A \zeta_A | \chi_C \zeta_{O'}), \\
 \varepsilon_A &= \text{either of } a_A^f, b_A^f, c_A^f, \quad \zeta = \text{either of } \chi, \xi, \eta.
 \end{aligned} \tag{8}$$

Thus we have two types of AO Coulomb integrals to be evaluated: $(\chi_A \chi_A | \zeta_C \zeta_{C'})$ and $(\chi_A \zeta_A | \chi_C \zeta_{C'})$ which contain $3d_{zz}$ and $3d_{yz}$ AO's.

When the AO integrals are evaluated, we substitute them into Eq. (8) and obtain the numerical values of MO Integrals. With these values put into Eq. (7) and (6) we get numerical values of a_{ik} , b_{ij} , c_{ij} etc. We may better utilize the iteration method to solve the complexity of simultaneous equations.

§ 3. S-T Intercombination Integral

After the modified MO's are obtained, we proceed to compute the S-T intercombination integral. It is given as⁴⁾;

$$\langle \Psi_T H_{LS} \Psi_S \rangle = i \left(\frac{\hbar}{2mc} \right)^2 \int V \left\{ \frac{\partial \phi_i^s}{\partial x} \frac{\partial \phi_j^s}{\partial y} - \frac{\partial \phi_i^s}{\partial y} \frac{\partial \phi_j^s}{\partial x} \right\} dv, \tag{9}$$

where ϕ_i^s and ϕ_j^s are the combining MO's belonging to the singlet and triplet states respectively. They are illustrated in Fig. 4 and Table IV of the reference 4.

Putting the AO expansion of ϕ^s as given by Eqs. (3), (4) and (5) into Eq. (9), we have, retaining only the first order terms,

$$\begin{aligned}
 I &= \int V \left\{ \frac{\partial \phi_i^s}{\partial x} \frac{\partial \phi_i^s}{\partial y} - \frac{\partial \phi_i^s}{\partial y} \frac{\partial \phi_j^s}{\partial x} \right\} dv \\
 &= \sqrt{\frac{\delta^6}{\pi}} \sqrt{\frac{2\delta'^7}{3\pi}} \delta \sum_{AB} \int_{r_a}^{z_a z_b} e^{-\delta r_a - \delta' r_b} V dv \sum_f \beta_{Bf} \{ y_a (\alpha_A^i b_{jf} - \alpha_A^j b_{if}) - x_a (\alpha_A^i c_{jf} - \alpha_A^j c_{if}) \}.
 \end{aligned} \tag{10}$$

One may remark that the coefficients a_{ik} do not come in Eq. (10). This is quite natural because they represent the mixing of $2p\pi$ MO of higher levels. In other words, this indicates that the adoption of SCF MO instead of Hueckel MO makes no matter to obtain far

better computation value of S-T intercombination intensity.

As for the form of potential V , we may assume the ordinary electrostatic potential composed of the nuclear attraction and electro-nic repulsion.⁷⁾

Numerical computation must be made now on the evaluation of AO Coulomb integrals involving $3d$ orbitals and then the determination of the expansion coefficients a_{ik} , b_{ij} , c_{ij} by the iteration method, and finally the intercombination integral.

Unfortunately publications concerning the evaluation of integrals containing $3d$ AO are very rare at present and we can find neither formula nor table utilizable directly for our calculation. Only in the table of Kotani *et al.*,⁸⁾ some formulae are given in the unresolved form, but they are not enough for our purpose.

Now we are studying to extend the formulae given by Kotani *et al.* to serve for our calculation. The result of numerical computation shall be published later.

In the succeeding paper, we shall discuss the emission spectra of the triplet states and the lifetime of phosphorescence of diphenyl. The method can be extended directly to other compounds and we may compare the result of our method with those of other workers.

Acknowledgement

The author wishes to express his sincere thanks to Prof. R. Daudel, Dr. R. Lefebvre of Centre de Chimie Théorique de France and equally to Prof. M. Kotani of the University of Tokyo for their very kind advice and encouragement.

Methods of Approximation of Molecular Integrals. I.

By Sigeru HUZINAGA

*General Education Department, Kyushu University,
Otsubo-machi, Fukuoka*

(Received June 26, 1958)

The Mulliken and the Sklar approximations for difficult molecular integrals have for some years been the subject of several investigations. So far, however, we are not provided with clear insight into these approximate methods and, accordingly, with sufficiently reliable criteria for the choice between them for each individual case.

In this paper a possible answer to the problem is presented by examining carefully the accuracies of these two methods. In addition, a new approximate method is proposed, which is useful when both the Mulliken and the Sklar approximations break down seriously.

§ 1. Introduction

Among various approximations for difficult molecular integrals the Mulliken¹⁾ and the Sklar²⁾ approximations are most widely used. Close examinations of these approximations have been the subject of several papers³⁾⁻¹⁰⁾.

In spite of those rather extensive studies, it seems that we have still no clear insight into the natures of these approximations and, accordingly, we have no sufficiently reliable criteria for the choice between them in actual molecular calculations. In the treatment of

the electronic levels of the benzene Parr, Craig and Ross³⁾ estimated three- and four-center integrals by the Sklar approximation. They examined the accuracies of the Sklar and the Mulliken approximations in reference to several two-center integrals and they stated "In these, and other similar cases, the success of the approximations perhaps varies too much to justify a choice between them; Sklar's method was therefore adopted to secure continuity with previous work." Eyring et al⁸⁾ arrived at a similar conclusion after their long effort to clarify the point of the present subject: "The tables for the individual integral values indicate that generalizations as to the direction or magnitude of errors caused by the approximations examined are dubious if not dangerous." Shull and Ellison^{4),9)} have made a distinct contribution by suggesting a qualitative criterion for the choice between the Mulliken and the Sklar approximations. Their suggestion, based on the experience of actual molecular calculations, is that "in future computations using these approximations, one should use that approximation for each integral which gives the lower value to that integral."

In this paper we present a possible answer to the present problem. We hope it is clear enough to justify a choice between the approximations for each individual case. In addition we shall see that a new approximate formula suggests itself in the course of examinations of the Mulliken and the Sklar approximations, which works well where both of these two approximations break down seriously.

§ 2. On Rüdénberg's Argument

Mulliken¹⁾ gives a general approximate formula for multicenter repulsion integrals in terms of two-center overlap and Coulomb integrals. His expression may be written,

$$\begin{aligned} [\chi_a \chi_b | \chi_c \chi_d] &= \int \chi_a(1) \chi_b(1) (1/r_{12}) \chi_c(2) \chi_d(2) d\tau_1 d\tau_2 \\ &\simeq \frac{1}{2} (\chi_a | \chi_b) (\chi_c | \chi_d) \{ [\chi_a \chi_a | \chi_c \chi_c] + [\chi_a \chi_a | \chi_d \chi_d] \\ &\quad + [\chi_b \chi_b | \chi_c \chi_c] + [\chi_b \chi_b | \chi_d \chi_d] \}, \end{aligned} \quad (2.1)$$

where

$$(\chi_a | \chi_b) = \int \chi_a(1) \chi_b(1) d\tau_1 \quad (\text{overlap integral}),$$

$$[\chi_a \chi_a | \chi_c \chi_c] = \int \chi_a(1) \chi_a(1) (1/r_{12}) \chi_c(2) \chi_c(2) d\tau_1 d\tau_2 \quad (\text{Coulomb integral}),$$

$\chi_a, \chi_b, \chi_c, \chi_d$ = atomic orbitals centered on nuclei a, b, c and d . It is easily seen that if we use the following approximate expression for the product $\chi_a(1) \chi_b(1)$,

$$\chi_a(1) \chi_b(1) \simeq \frac{1}{2} (\chi_a | \chi_b) \{ \chi_a(1) \chi_a(1) + \chi_b(1) \chi_b(1) \}, \quad (2.2)$$

we obtain the expression (2.1). This is the core of the Mulliken approximation. Mulliken suggested his formula on an intuitive basis and, subsequently, Rüdénberg¹¹⁾ succeeded in showing that this approximation corresponds to the leading term in an infinite series development. We shall recapitulate here Rüdénberg's argument in a simple case of two homonuclear centers a and b . Let

$$\chi_{a1}, \chi_{a2}, \dots, \chi_{ak}, \dots$$

be a complete set of orthogonalized real orbitals on center a and analogously

$$\chi_{b1}, \chi_{b2}, \dots, \chi_{bk}, \dots$$

on center b . Then we may have the expansions, for example,

$$\left. \begin{aligned} \chi_{a1}(1) &= \sum_{k=1}^{\infty} (\chi_{a1} | \chi_{bk}) \chi_{bk}(1), \\ \chi_{b1}(1) &= \sum_{k=1}^{\infty} (\chi_{b1} | \chi_{ak}) \chi_{ak}(1), \end{aligned} \right\} \quad (2.3)$$

whence:

$$\begin{aligned} \chi_{a1}(1) \chi_{b1}(1) &= \frac{1}{2} \sum_{k=1}^{\infty} (\chi_{a1} | \chi_{bk}) \{ \chi_{a1}(1) \chi_{ak}(1) + \chi_{b1}(1) \chi_{bk}(1) \} \\ &= \frac{1}{2} (\chi_{a1} | \chi_{b1}) \{ \chi_{a1}(1) \chi_{a1}(1) + \chi_{b1}(1) \chi_{b1}(1) \} \\ &\quad + \frac{1}{2} (\chi_{a1} | \chi_{b2}) \{ \chi_{a1}(1) \chi_{a2}(1) + \chi_{b1}(1) \chi_{b2}(1) \} \\ &\quad + \dots \end{aligned} \quad (2.4)$$

The first term is nothing but the Mulliken approximation (2.2). This justification of the Mulliken approximation seems quite lucid mathematically but it does not provide us practical criteria of the approximation useful for each individual case encountered in actual molecular calculations. Concerning this point, one might suggest an "improvement" of the Mulliken approximation by including the second term of the expansion (2.4). This "improvement" has an apparent disadvantage. To fix the idea, let us suppose our χ_{a1} be a $1s$ orbital. Then it is natural to take a $2p\sigma$ orbital for χ_{a2} . Thus we have to estimate additional overlap and Coulomb integrals involving $2p\sigma$. Actually, it turns out that such a straightforward inclusion of a second term does not constitute an "improvement" at all.

One can see this, for example, by evaluating the following two-center integrals using first two terms in (2.4);

$$[a|\chi_a\chi_b] = \int (1/r_{a1})\chi_a(1)\chi_b(1)d\tau_1$$

(nuclear attraction integral),

$$[\chi_a(1)\chi_b(1)|\chi_a(2)\chi_b(2)]$$

$$= \int \chi_a(1)\chi_b(1)(1/r_{12})\chi_a(2)\chi_b(2)d\tau_1d\tau_2$$

(exchange integral).

For these cases the Mulliken approximation yields too large values in large nuclear separation R_{ab} as shown in Table I and Table II, and it is easily seen that the inclusion of the second term makes them still larger. Barker and Eyring⁷⁾ have revealed another example showing that the mathematically elegant discussion of R udenberg does not necessarily lead us to practically useful approximations. This situation seems to indicate that it would be rather difficult to proceed purely mathematically to reach our desired clear-cut answer to the present problem. Probably we should recede a little and start again from more or less intuitive bases after the manner of Mulliken's original reasoning.

§ 3. Types of Approximation

In the present treatment, we shall start by recalling Ellison's important observation⁹⁾ that "in general, good approximations of AO interaction integrals can be obtained only by securing good approximate representations of the actual charge distributions involved."

Now let the atomic orbitals χ 's be simply 1s hydrogen-like functions such as

$$\chi_a(1) = s_a(1) = (Z^3/\pi)^{1/2} \exp(-Zr_{a1}), \quad (3.1)$$

where Z is the effective nuclear charge. Then the "charge distribution" $\chi_a(1)\chi_b(1)$ is explicitly written

$$s_a(1)s_b(1) \sim \exp[-Z(r_{a1} + r_{b1})]. \quad (3.2)$$

Here, it is important to recognize that this function is "flat" on the line connecting two centers a and b , as pictured in Fig. 1(a). With this in mind, we shall try to examine the natures of the Mulliken and the Sklar approximations:

$$(M) \quad s_a(1)s_b(1) \simeq \frac{1}{2}(s_a|s_b)\{s_a(1)s_a(1) + s_b(1)s_b(1)\}, \quad (3.3)$$

$$(S) \quad s_a(1)s_b(1) \simeq (s_a|s_b)s_m(1)s_m(1), \quad (3.4)$$

where m is the middle point between a and b . Corresponding charge distributions are pictured in Fig. 1(b) and (c), respectively. It is clearly observed that the resemblances between these two approximate charge distributions and the actual one are rather poor, especially at large internuclear separation (right-hand side of Fig. 1). Looking at these three figures, (a), (b), (c), we naturally arrive at an idea of increasing the resemblance by

Fig. 1.

superposing (b) to (c) with the resulting figure (d). More precisely, this means to take

$$(MS) \quad s_a(1)s_b(1) \simeq \frac{1}{2}(s_a|s_b)\{s_a(1)s_a(1) + s_b(1)s_b(1) + s_m(1)s_m(1) + s_b(1)s_b(1)\}. \quad (3.5)$$

This formula may be regarded as one of possible hybrids of the Mulliken and the Sklar approximations and we shall call this here the MS approximation tentatively.

At first sight, it is expected that the use of the approximate formula (3.5) yields the results always better than those of the Mulliken and the Sklar approximations because the figure (d) seems to have the best resemblance to the actual distribution (a) in Fig. 1. Actually, however, this is not the case. A nuclear attraction integral $[a|s_a s_b]$ presents a notable example: we observe in Table I that the Sklar approximation is consistently superior to other two approximations for this integral. What is the reason for this rather perplexing situation? The reason lies in the fact that the molecular integrals interested here are not integrals over simple products of certain charge distributions, as is the case

Table I. $[a|s_a s_b]/Z$ (in au)

$q=ZR$	Actual value	M	S	MS

for overlap integrals, but contain the “weight factor” such as $(1/r_{a1})$ or $(1/r_{12})$ in the integrands. In the next section we shall try to explain more clearly the implication of this statement.

§ 4. Approximate and Actual Values of Various Molecular Integrals (Part I)

In this section we compare values calculated using the three types of approximation, (M), (S) and (MS), with actual values of two- and three-center 1s orbital integrals, where the centers are located linearly with equal distances. Fig. 2 is prepared for the purpose of easy identification of the definition of each integral.

Group I. Nuclear attraction integrals.

(I- α) $[a|s_a s_b] = \int (1/r_{a1}) s_a(1) s_b(1) d\tau_1 .$

(I- α -M): $\frac{1}{2}(s_a|s_b)\{[a|s_a s_a] + [a|s_b s_b]\} ,$

Fig. 2.

(I- α -S): $(s_a|s_b)[a|s_m s_m] ,$
(I- α -MS): $\frac{1}{3}(s_a|s_b)\{[a|s_a s_a] + [a|s_m s_m] + [a|s_b s_b]\}$
 $= \frac{1}{3}\{2(M) + (S)\} .$

$[a|s_a s_b]$ is a simple two-center integral which can be evaluated exactly. Table I shows that the Mulliken approximation gives always higher values and the departure from actual values grows seriously for larger values of $q=ZR$. At those large distances the first term $(s_a|s_b)[a|s_a s_a]$ of (I- α -M) makes dominant contribution. Since $[a|s_a s_a]$ is a constant, the above mentioned tendency of the Mulliken approximation means that the decay of the factor $(s_a|s_b)$ is too slow as compared with that of the actual values of $[a|s_a s_b]$. Let us try to speak a little more pictorially. As may be seen from (3.2) and Fig. 1(a), the actual shape of $s_a(1)s_b(1)$ is something like an elongated spindle. In the Mulliken approximation the half of the charge distribution is gathered to a spherical distribution $s_a(1)s_a(1)$ centered at a and another half to $s_b(1)s_b(1)$. Then the charge distribution $s_a(1)s_a(1)$ at a tends to exaggerate the effect of the “weight” $(1/r_{a1})$ centered also at a . Thus, the effect of $[a|s_a s_a]$ becomes predominant more and more for larger distances because of insufficient suppressive effect of $(s_a|s_b)$ which is a simple integral over $s_a(1)s_b(1)$ lacking any damped weight factor and decaying too slowly.

In the Sklar approximation the actual charge distribution is replaced simply by a single charge cloud $s_m(1)s_m(1)$ at the middle point m between a and b , and there exists finite distance between the center of Coulomb potential $(1/r_{a1})$ and that of the interacting charge cloud. According to Table I, this situation works rather favorably at least for intermediate values of q . It should be noted, however, that (I- α -S) yields consistently smaller values (except for $q=2$ and 3) and the discrepancies

seem to become larger with increasing distance. This may be understood again by considering the effect of the weight $(1/r_{a1})$: in the actual distribution $s_a(1)s_b(1)$ there survives finite portion of the distribution in the deep "hole" of $(-)(1/r_{a1})$ but in the Sklar approximation there lies only rapidly vanishing tail of $s_m(1)s_m(1)$.

Finally, as for the MS approximation, it may easily be inferred that this approximation should yield too large values because the fatal defect of the Mulliken approximation mentioned above is remedied only insufficiently here.

(I-β) $[a|s_b s_c] = \int (1/r_{a1}) s_b(1) s_c(1) d\tau_1.$

(I-β-M): $\frac{1}{2}(s_b|s_c)\{[a|s_b s_b] + [a|s_c s_c]\},$

(I-β-S): $(s_b|s_c)[a|s_m s_m],$

(I-β-MS) $\frac{1}{3}\{2(M) + (S)\}.$

In this case the center a of the troublesome weight factor $(1/r_{a1})$ lies outside of main portion of the charge distribution $s_b s_c$ as contrasted to the case of $[a|s_a s_b]$. Nevertheless, it is probable that the charge concentration $s_b(1)s_b(1)$ in the Mulliken and the MS approximations is still prone to exaggerate the effect of $(1/r_{a1})$. Thus, in view of the detailed discussion in the case of $[a|s_a s_b]$, it is quite natural to expect that the general tendency that the Mulliken approximation gives larger values and the Sklar approximation yields smaller

values will still be observed but the degree of diversity of the actual and approximate values will become less conspicuous in this case of $[a|s_b s_c]$ as compared with the case of $[a|s_a s_b]$. These expectations are completely confirmed in Table II.

(I-γ) $[b|s_a s_c] = \int (1/r_{b1}) s_a(1) s_c(1) d\tau_1.$

(1-γ-M): $(s_a|s_c)[b|s_a s_a],$

(I-γ-S): $(s_a|s_c)[b|s_b s_b],$

(I-γ-MS): $\frac{1}{3}\{2(M) + (S)\}.$

This integral seems to deserve careful considerations because both (I-γ-M) and (I-γ-S) provide only very poor approximate values. Let us try to "predict" characteristic features of the Mulliken and the Sklar approximations for this case. Imagine that we dig a deep hole of the Coulomb potential $(-)(1/r_1)$ at the middle point between a and b in each diagram of Fig. 1. Comparison of the diagrams thus obtained immediately render us to predict that the Mulliken approximation should give smaller values and, on the contrary, the Sklar approximation should give badly exaggerated values. Our reasoning in this case is quite similar to that used in (I-α) and (I-β) and it would be unnecessary to describe it in detail. Table III tells us that our predictions are quite right. It should be remarked that both the Mulliken and the Sklar approximation break down seriously especially for large

Table II. $[a|s_b s_c]/Z$ (in au)

values of q and the MS approximation yields consistently rather good results.

Group II. Hybrid integrals.

(II- α) $[s_a s_a | s_a s_b]$

$$= \int s_a(1) s_a(1) (1/r_{12}) s_a(2) s_b(2) d\tau_1 d\tau_2 ,$$

(II- β) $[s_a s_a | s_b s_c]$

$$= \int s_a(1) s_a(1) (1/r_{12}) s_b(2) s_c(2) d\tau_1 d\tau_2 ,$$

(II- γ) $[s_b s_b | s_a s_c]$

$$= \int s_b(1) s_b(1) (1/r_{12}) s_a(2) s_c(2) d\tau_1 d\tau_2 ,$$

There are obvious relationships between the integrals of Group I and Group II. It is clear that, if $s_a(1)s_a(1)$ or $s_b(1)s_b(1)$ is contracted to a δ -function-like distribution in (II- α), (II- β),

(II- γ), we immediately obtain (I- α), (I- β), (I- γ), respectively. Conversely, we may say that the integrals of Group II can be obtained by smearing the point charge in Group I to form a spherical distribution $s_a(1)s_a(1)$ or $s_b(1)s_b(1)$. These observations serve to clarify the behaviors of our three approximations for the hybrid integrals in question. Thus, it is expected that the general situation would remain essentially unchanged but several distinct features remarked for the nuclear attraction integrals (Group I) would be moderated here because the troublesome "singularity" of $(1/r_{a1})$ or $(1/r_{b1})$ in Group I is somewhat blurred in Group II. In fact, we can easily notice close correspondences and resemblances between the results exhibited in Tables I, II, III and Tables IV, V, VI.

Group III. Exchange integrals.

$$(III-\alpha) \quad [s_a s_b | s_a s_b]$$

$$= \int s_a(1) s_b(1) (1/r_{12}) s_a(2) s_b(2) d\tau_1 d\tau_2.$$

$$(III-\alpha-M): \quad \frac{1}{2}(s_a | s_b)^2 \{ [s_a s_a | s_a s_a] + [s_a s_a | s_b s_b] \},$$

$$(III-\alpha-S): \quad (s_a | s_b)^2 [s_m s_m | s_m s_m],$$

$$(III-\alpha-MS): \quad \frac{1}{3}(s_a | s_b)^2 \{ 3[s_a s_a | s_a s_a] \\ + 4[s_a s_a | s_m s_m] + 2[s_a s_a | s_b s_b] \}.$$

This integral brings about a new feature. Let us first examine the results of Table VII. The most interesting point is that both (III- α -M) and (III- α -S) yield higher values for larger q . So far, this is never the case. Mathematically, this is a direct consequence of the fact that both approximate formulas contain a constant term, $[s_a s_a | s_a s_a] \equiv [s_m s_m | s_m s_m]$. In this respect, (III- α -M) is quite similar to (I- α -M) and (III- α -S) to (I- γ -S). Some reflections on the shapes of the actual and the approximate charge distributions seem to be useful again for the present case. $[s_a s_b | s_a s_b]$ describes the Coulomb interaction between two overlapping charge distributions, $s_a(1)s_b(1)$ and $s_a(2)s_b(2)$, of an elongated shape. In the Sklar approximation this is approximated by the interaction between two identical spherical charge distributions centered always at the middle point m between a and b . Just as in $[b | s_a s_c]$ (I- γ) and $[s_b s_b | s_a s_c]$ (II- γ), we are bound to overestimate the "weight" $(1/r_{12})$ under such a condition, especially for large q . Thus, the Sklar approximation gives consistently higher values in the present case. Also in the Mulliken approximation the term $[s_a s_a | s_a s_a]$, representing the interaction between two identically overlapping spherical charges, gives rise to the same kind of departure from actual values but the existence of

another term $[s_a s_a | s_b s_b]$ which represents the interaction between two distant charge distributions prevents to some extent serious breakdown of the approximation as compared with the Sklar approximation. Inferring in this way, we may understand that the MS approximation yields always values of tolerable accuracy. It is of interest to note that for $q > 6$ (III- α -MS) gives lower values than either those of (III- α -M) and of (III- α -S).

$$(III-\beta) \quad [s_a s_b | s_a s_c]$$

$$= \int s_a(1) s_b(1) (1/r_{12}) s_a(2) s_c(2) d\tau_1 d\tau_2.$$

We may obtain this type of integral from $[s_a s_b | s_a s_b]$ (III- α) by making one of the two $s_a s_b$'s longer than the other, or from $[s_a s_a | s_a s_c]$ (II- α) by elongating the spherical charge distribution $s_a s_a$ to $s_a s_b$. From such view-points, we may expect the following features. (1) In the Mulliken approximation the tendency of departure from the actual values will be more or less similar to the cases of $[s_a s_b | s_a s_b]$ and $[s_a s_a | s_a s_b]$, namely the approximate values will be smaller at the beginning and eventually surpass the actual values because of the overlapping of two spherical charge distributions at a . (2) In the Sklar approximation, a serious overestimation exhibited in the case of $[s_a s_b | s_a s_b]$ will be avoided because there now exists finite separation between centers of the two approximate spherical charge distributions, but this very separation might bring about a tendency of giving smaller values in the long run in analogous manner encountered in the case of $[a | s_a s_b]$ and $[s_a s_a | s_a s_b]$. Unfortunately, these expectations are not fully confirmed in Table VIII, because comparisons are performed for only three values of q , 2, 4, 6. Nevertheless, the present author believes that

Table VIII. $[s_a s_b | s_a s_c]/Z$ (in au)

$q=ZR$	Actual value	M	S	MS
2.0	0.05121	0.04785	0.06155	0.05185
4.0	0.0006539	0.0005995	0.0008204	0.0006711
6.0	4.769×10^{-6}	4.596×10^{-6}	5.645×10^{-6}	5.068×10^{-6}

Table IX. $[s_a s_b | s_b s_c]/Z$ (in au)

$q=ZR$	Actual value	M	S	MS
2.0	0.1412	0.1483	0.1465	0.1490
4.0	0.009128	0.01115	0.0008867	0.01066
6.0	0.0004364	0.0005775	0.0003695	0.0005101

the above expectations should turn out essentially correct, if comparisons are made for larger values of q . It is of interest to note that the MS approximation yields rather excellent values.

(III- γ) $[s_a s_b | s_b s_c]$

$$= \int s_a(1) s_b(1) (1/r_{12}) s_b(2) s_c(2) d\tau_1 d\tau_2.$$

This integral represents the interaction of two elongated charge distributions, $s_a(1)s_b(1)$ and $s_b(2)s_c(2)$, with their end tails overlapped. The Mulliken approximation will exaggerate this overlapping by placing two spherical charge distributions at b . On the contrary, the Sklar approximation will tend to yield smaller values because two spherical charge distributions are put separately here. Table IX seems to confirm these expectations.

§ 5. Rules of Choice

Anyone who is patient enough to follow rather tiresome discussions in the preceding section may recognize that the line of reasoning is very simple and almost trivial but, none the less, seems to be useful in some cases. It is based upon intuitive comparisons of the forms of the actual and approximate charge distributions with accompanied consideration of the effect of the "weight" factor such as $(1/r_{a1})$ or $(1/r_{12})$ in each individual integral. It may be possible, if we wish, to write down the "rules" explicitly in fixed sentences but we will not do so here. The reason is that we believe we had better keep the manner of reasoning in mind as a working principle to be applied flexibly to individual cases.

Here, let us try to find a possible explanation of a rule of choice between the Mulliken and the Sklar methods for interactions involving symmetrical charge distributions proposed empirically by Ellison⁹⁾: "Here, the best procedure is to utilize the lower value as given by the two methods for each integral." In the preceding section it is observed that we obtain exaggerated values when approximate charge distributions are placed in such a way that the Coulomb interaction, $(1/r_{a1})$ or $(1/r_{12})$, is apt to be overestimated under insufficient suppression due to the factor, $(s_a|s_b)$ or $(s_a|s_b)^2$. In many cases we can identify terms mainly responsible for such troubles in approximate

formulas and it seems almost always certain that the higher of two approximate values from the two methods comes directly from such troublesome terms in respective approximate formula. Because of this distinct cause, it seems that deviations take place more seriously to larger value side than to the opposite side. Presumably here lies one of possible explanations of the rule of Ellison and Shull. The most typical examples are the Sklar approximations for $[b|s_a s_a]$ (I- γ), $[s_b s_b | s_a s_a]$ (III- γ) and $[s_a s_b | s_a s_b]$ (III- α). (See Tables III, VI, VII). Another example is found in the Mulliken approximation for $[a|s_a s_b]$ (I- α) or $[s_a s_a | s_a s_b]$ (II- α). (See Tables I, IV). Here the "lower value" rule favors the Sklar approximation.

In the present paper, we have three approximate methods. In addition to the Mulliken and the Sklar methods, we have proposed a new approximation which is properly regarded as one of possible hybrids of the Mulliken and the Sklar approximations. This third method works rather well where both parent methods break down seriously. As will be shown in the following sections, we can be definite about the choice among these three methods in some cases, but in some other cases we are not quite sure about the matter. In such cases we may rely upon the "lower value" rule explained above or upon the MS approximation.

§ 6. Approximate and Actual Values of Various Molecular Integrals (Part II)

Taylor¹²⁾ in his treatment of the linear H_4 system calculated accurately various multi-center integrals. We shall make use of them to check the accuracies of our three approximation methods. The accurate values of integrals are listed in Table X together with the approximate values given by our three methods. Before we begin to examine Table X, let us try to choose the best method for each integral. Diagrams similar to those in Fig. 2 may easily be drawn for the integrals in the table. The nuclei a, b, c, d are spaced linearly at equal intervals ($R=1.4a_u$), the equilibrium internuclear separation H_2 . Looking at those diagrams, we may foresee the following features. (1) The Sklar approximation will be successful for $[a|s_b s_c]$, $[a|s_b s_a]$, $[a|s_c s_a]$; $[s_a s_a | s_b s_c]$, $[s_a s_a | s_b s_a]$, $[s_a s_a | s_c s_a]$; $[s_a s_b | s_b s_c]$, be-

cause these integrals belong essentially to the same type as $[a|s_b s_c]$ (I- β) and $[s_a s_a|s_b s_c]$ (II- β) in § 4. (2) For $[b|s_a s_c]$, $[b|s_a s_d]$; $[s_b s_b|s_a s_c]$, $[s_a s_d|s_b s_c]$, the Mulliken approximation will yield lower values and the Sklar approximation will give too high values. Probably the MS approximation will give the best approximate values. (3) As for the remaining integrals, we cannot be quite certain about selection of a single method for each integral. The interval between nuclei, $R=1.4$ au, is not large enough to permit us to say something definite about the behaviors of the three approximate methods. Here we may use the "lower value" rule between the Mulliken and the Sklar approximations or rely upon the MS approximation.

Table X. Taylor's integrals. (in eV)

* This table includes the three- and four-center integrals listed in Table II of Parr, Craing and Ross³⁾. They used the approximate values given by the Sklar method. Values due to the Mulliken and the MS approximations can easily be calculated by using numerical values in their Table II. $(pq|rs)$ is the Coulomb-exchange integral $\int \pi_p^*(1)\pi_r^*(2)(e^2/r_{12})\pi_q(1)\pi_s(2)d\tau_1 d\tau_2$, where π_p is the $2p\pi$ orbital on the p th carbon atom, and the carbon atom are numbered consecutively around the ring as is shown in Fig. 3.

§ 7. Approximate and Actual Values of Various Molecular Integrals (Part III)

So far, we have concerned exclusively with 1s orbitals. Practically, however, it would be more important to examine the approximate methods in the case of difficult integrals involving $2p\pi$ orbitals such as

$$(2p\pi)_a = \pi_a(1) \\ = (\delta^5/\pi)^{1/2} r_{a1} \sin \theta_{a1} \cos \varphi_{a1} \exp(-\delta r_{a1}).$$

Unfortunately, there have been found no accurate values of the multicenter integrals available to the present author. We believe, however, that examinations of the approximate methods with reference to available two-center integrals are useful enough to draw some general conclusions at least for homonuclear systems. Comparisons are made between the actual¹³⁾ and the approximate values in Table XI ($[a|\pi_a\pi_b]$), Table XII ($[\pi_a\pi_a|\pi_a\pi_b]$) and Table XIII ($[\pi_a\pi_b|\pi_a\pi_b]$). These are to be examined in relation to Table I ($[a|s_a s_b]$), Table IV ($[s_a s_a|s_a s_b]$) and Table VII ($[s_a s_b|s_a s_b]$) respectively. It is immediately noticed that, except for smaller values of $q = \delta R$ devoid of practical importance, the parallelisms between the two corresponding tables are very close. This suggests strongly that the line of reasoning successful for 1s orbitals could be applied also to $2p\pi$ orbitals without suffering any essential modification.

Parr, Craig and Ross³⁾ in their famous treatment of the benzene molecule calculated three- and four-center integrals by using the Sklar approximation. It would be of interest to try to check the accuracies of adopted approximate values because it is shown by them that the inclusion of those multicenter integrals affects the final result quite appreciably. Table XIV contains the relevant numerical values and Fig. 3 will be helpful for the inspections of the results displayed in the table. In view of the discussion of § 5 we may ex-

pect that the "lower value" criterion of Ellison and Shull should work well for the present case. This criterion favors the Mulliken approximation overwhelmingly here as is seen in Table XIV. Values due to the MS approximation are given for the integrals for which the MS method is expected to be the best. We may easily pick up those integrals

Fig. 3.

8.0	0.0001345	0.0001359	0.0002081	0.0001345

by inspecting the corresponding diagrams in Fig. 3 a little carefully. For example, the type of (11|26) is already familiar to us. The integrals such as (13|24), (13|25), (14|25) present new features. In those integrals the two interacting charge distributions are crossing each other as indicated in Fig. 3. It is easily imagined that the Sklar approximation should give too exaggerated values and the Mulliken approximation too lower values for those cases. In this connection, especially striking is the way in which values as given by the Mulliken and the Sklar approximations differ each other for the so-called penetration integrals. The most conspicuous case is (1:26), where the value due to the Sklar approximation is almost ten times larger than that of the Mulliken approximation. It seems necessary to pay special attentions to these integrals. The definition of the penetration integrals is

$$(\dot{p}:rs) = - \int U_p(1) \pi_r^*(1) \pi_s(1) d\tau_1,$$

where $U_p(1)$ is the potential on electron 1 caused by a neutral p th carbon atom. We may obtain this type of integrals by replacing the Coulomb potential $(1/r_p)$ with $U_p(r)$ in the usual nuclear attraction integral. It is quite important to notice that the new "weight" function $U_p(r)$ decays much faster than $(1/r)$. Then, it follows that approximate values are bound to be quite sensitive to the location of the concentrated charge distributions in individual approximations. Let us consider the integral (1:23) as an example. The actual distribution of the electron feeling the potential $U_1(r)$ is extending over the region between the points 2 and 3 (See Fig. 3, (1:23)). In view of the steep dependence of $U(r)$ on r , the "tail" of the charge distribution around the point 2 would essentially determine the actual value of the penetration integral (1:23). In the Mulliken method the half of the distribution is concentrated at 2 and this is bound to exaggerate the value of the integral. On the other hand, the whole charge is gathered on the middle point between 2 and 3 in the Sklar method and this procedure may give too lower value. These reasonings seem to be justified if we note that the discrepancy between the results as given by the two methods is diminished appreciably for (1:24) and still lesser for (1:25), where the Sklar

method gives larger value probably because the distances are equal here between 1 and 2 and between 1 and the middle point of 2 and 4. Now let us return to (1:26). In this case the middle point between 2 and 6 (the charge center of the Sklar method) locates very closely to the potential origin 1, while the points 2 and 6 are equally far apart from 1. Then, the numerical result mentioned above and shown in Table XIV is now accepted as quite natural one. Situation in the remaining two integrals, (1:34), (1:35) may also be understood analogously.

In Table XIV the presumably best values are printed in boldface. As a whole, the modifications of approximate values proposed here are not insignificant and it is hoped to repeat the calculation of the electronic levels of the benzene molecule with these new values of integrals.

Concluding Remark

In this paper the discussions are limited within homonuclear systems involving 1s or $2p\pi$ orbitals only, not because we are not capable of treating other cases but because we wish to expose the essential features of our way of reasoning about the present subject as clearly as possible. In the subsequent papers we shall treat several other cases of practical importance.

The Visco-elastic Properties of Network Structure

III. Normal Stress Effect (Weissenberg Effect)

Misazo YAMAMOTO

Department of Chemistry, Faculty of Science, Kyoto University

(Received July 2, 1958)

A statistical mechanical theory of the so-called Weissenberg effect (or, normal stress effect) is presented. We adopt the weakly coupled rubber-like network model which we have formulated and applied to investigate the shearing and the tensile viscosity of concentrated solutions of linear high polymers. When the elastico-viscous liquid is compelled to stationary shearing flow, our theory shows that an additional normal tension arises in the direction of flow owing to the orientation of the network structure in addition to the usual shearing stress. Furthermore if the fluid is in a concentric circular motion with the angular velocity gradient in the radial or the axial direction, each doughnut-shaped piece along a flow line behaves as a stretched rubber loop due to the said additional tension. As the result the inner bulk of the liquid is squeezed. The pressure increases as one approaches to the rotational axis. Such pressure distribution is calculated for the instruments of three types, i.e., the coaxial cylinder, the parallel plate and cone and plate instrument. The results are at least qualitatively in good agreement with various experimental results reported by Roberts, Philippoff, Rivlin, Kurata, Kotaka and Tamura and others.

§ 1. Introduction

In the previous papers^{1),2)} of this series we have developed a molecular theory on visco-elastic properties of amorphous polymeric substances as well as concentrated polymer solutions making use of the weakly coupled rubber-like network model. A general formulation was given in the first paper, and in the next paper we treated the shearing and the tensile viscosity. In the present paper, we shall consider the application of our theory to the so-called normal stress effect (Weissenberg effect).

Let us consider a liquid put into the gap between coaxial cylinders and subjected to a continuous shear. If the liquid is purely viscous and inelastic, a concave surface may be observed because of the centrifugal force. On the contrary, in the case of elastico-viscous liquids, the liquid often climbs up around the inner cylinder. The phenomena of this type which are commonly termed "Weissenberg effects" have been investigated with increasing interest from rheological point of view since 1946.³⁾

On the other hand, it has long been remarked that when a cylindrical piece of certain elastic materials such as steel, lead or

vulcanized rubber are subjected to a torsional couple, the cylinder shows an anomalous effect termed "Poynting effect" or an elongation proportional to the square of the amount of torsion.⁴⁾ These two effects, however, are essentially the same in nature and are characterized by the non-uniformity and anisotropy in the normal components of the stress tensor. Hence we will use in this paper the term "normal stress effects".

A quantitative measurement of normal stresses in steady flow has first been carried out by Roberts by using a cone-plate instrument with a narrow gap (the Weissenberg rheogoniometer)⁵⁾, in which the rate of shear, λ , remains constant throughout the gap. He has determined separately the normal pressures (i.e. the negative sign of normal stresses), P_r , P_θ and P_φ , in three directions of the polar coordinate system, and found the following relations between them:

$$P_r = P_\theta, \quad (1)$$

$$P_\varphi - P_r = P_\varphi - P_\theta \quad (2)$$

$$= \frac{\partial P_i}{\partial \log r} = -C, \quad (i=r, \theta, \varphi) \quad (3)$$

where C is a positive constant and depends only on the rate of shear, λ , in the manner

shown in Fig. 1. He has also noted that the relation (1) was favorably in agreement with the *cross elasticity* theories,⁶⁾ but not with the *cross viscosity* theories.⁷⁾ After that, the normal stress measurements have been conducted by many investigators:⁸⁾⁻¹³⁾ i.e. by Markovitz, Philippoff and their coworkers with the same type of instrument as above; by Padden and DeWitt with a coaxial cylinder instrument; and Greensmith and Rivlin, and Kurata, Kotaka and Tamura with parallel plate instruments. As a result of these experiments, a considerable amount of the normal stress data are now accumulated for concentrated solutions of high polymeric substances.

Fig. 1. Rate of shear dependence of the Weissenberg effect. (Roberts)

There are number of phenomenological theories of the effect,^{6), 7), 14-18)} but the treatments for molecular point of view are still scarce. In the paper of Zimm,²⁰⁾ it was noted that the elastic stress tensor for an isolated polymer coil in solutions also involves normal stress components, but they appear so small that we can not detect them by the present accuracy of experiment. Thus in this paper, we will develop a molecular theory of the normal stress effect in concentrated polymer solutions and/or in amorphous polymers following the weakly coupled network model proposed in the previous papers of this series,^{1), 2)} and make an interpretation of some existing data. We start with the stress tensor for a simple shearing flow. Besides the shearing stress component it has an

additional tensile stress component in the flow-direction which is proportional to the square of the velocity gradient (§ 2). This additional tension results in non-uniformity and anisotropy in the distribution of the pressure for simple circular motions of the said three types (§ 3 and § 4). This gives a satisfactory interpretation of the Weissenberg effect. Although Lodge presented recently a theory²¹⁾ similar in nature to ours, the overlap between his theory and ours seems only slight.

§ 2. General Consideration

We begin with general remarks on the stress tensor in steady flow. For the flowing pattern of fluids, we assume that:

- i) Motion of the liquid is irrotational, laminar steady flow.
- ii) Velocity of the liquid has no components in the radial and vertical directions, and therefore flow lines are simply concentric circles around an axis.

In what follows, the cylindrical coordinates, (r, φ, z) , are adopted in the cases of coaxial cylinder and parallel plate instruments, and the polar coordinates, (r, θ, φ) , in the case of cone-plate instrument. As is easily seen from the above assumptions, the motion of the liquid can be described as a steady, simple shearing flow in the φ -direction and the velocity gradient is generated in the r -, z - and θ -directions in the coaxial cylinder, parallel plate and cone-plate instruments, respectively.

For this simple shearing flow, let us define the steady stress tensor, $s(\lambda) = (s_{ij}(\lambda))$, as a function of the velocity gradient, λ . The explicit form of the function $s(\lambda)$ corresponding to our weakly coupled network model will be given at the end of this section. The distribution of the velocity gradient, λ , and inner hydrostatic pressure, P , which is considered to be a function of coordinates, may be determined by Euler balancing equations.

The Euler equations for steady flow are written down in the cylindrical coordinates

$$\frac{\partial \sigma_{rr}}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{\varphi r}}{\partial \varphi} + \frac{\partial \sigma_{zr}}{\partial z} + \frac{\sigma_{rr} - \sigma_{\varphi\varphi}}{r} + R = 0, \quad (4a)$$

$$\frac{\partial \sigma_{r\varphi}}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{\varphi\varphi}}{\partial \varphi} + \frac{\partial \sigma_{z\varphi}}{\partial z} + 2 \frac{\sigma_{r\varphi}}{r} + \Phi = 0, \quad (4b)$$

$$\frac{\partial \sigma_{rz}}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{\varphi z}}{\partial \varphi} + \frac{\partial \sigma_{zz}}{\partial z} + \frac{\sigma_{rz}}{r} + Z = 0, \quad (4c)$$

and in the polar coordinates,

$$r \frac{\partial \sigma_{rr}}{\partial r} + \frac{\partial \sigma_{\theta r}}{\partial \theta} + \frac{1}{\sin \theta} \frac{\partial \sigma_{\varphi r}}{\partial \varphi} + 2\sigma_{rr} - \sigma_{\theta\theta} - \sigma_{\varphi\varphi} - \cot \theta \cdot \sigma_{\theta r} + Rr = 0, \quad (5a)$$

$$r \frac{\partial \sigma_{r\theta}}{\partial r} + \frac{\partial \sigma_{\theta\theta}}{\partial \theta} + \frac{1}{\sin \theta} \frac{\partial \sigma_{\varphi\theta}}{\partial \varphi} + 3\sigma_{r\theta} + \cot \theta \cdot (\sigma_{\theta\theta} - \sigma_{\varphi\varphi}) + \Theta r = 0, \quad (5b)$$

$$r \frac{\partial \sigma_{r\varphi}}{\partial r} + \frac{\partial \sigma_{\theta\varphi}}{\partial \theta} + \frac{1}{\sin \theta} \frac{\partial \sigma_{\varphi\varphi}}{\partial \varphi} + 3\sigma_{r\varphi} + 2 \cot \theta \cdot \sigma_{\varphi\theta} + \Phi r = 0, \quad (5c)$$

where (R, Φ, Z) and (R, Θ, Φ) are the external body forces acting on the bulk of liquid.

Let the liquid be constrained to the simple shearing flow in the x -direction with a constant velocity gradient, λ , in the y -direction. The deformation tensor, $e(t)$, is written as

$$e(t) = \begin{pmatrix} 1 & \lambda t & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (6)$$

We shall employ the weakly coupled network model, which has been treated in the two previous papers, in the determination of the stress tensor for this deformation. For the time being, we assume that the network is constructed of so-called Gaussian chains and breaks with a constant rate $\beta(r, N) = \beta$. (The definition of the "chain-breakage coefficient" $\beta(r, N)$ was given in § 4 of Part 1.¹¹) More general case will be treated afterward. The stress tensor,

$$s = s_n + P\mathbf{1}, \quad (7)$$

satisfies the equation of motion

$$\frac{ds_n}{dt} = \frac{de}{dt} \cdot e^{-1} \cdot s_n + s_n \cdot e^{\dagger-1} \cdot \frac{de^{\dagger}}{dt} + \left(\frac{ds_n}{dt} \right)^{b,r}, \quad (8)$$

with the isotropic inner hydrostatic pressure, P . $(ds_n/dt)^{b,r}$ expresses the creation of stress due to breakage and reformation of the junctions. Here if we assume that the instantaneous distribution of the reformed chains is isotropic, the term $(ds_n/dt)^{b,r}$ in the right-hand side of Eq. (8) may be written as

$$(ds_n/dt)^{b,r} = \beta(\sigma_0 \mathbf{1} - s_n). \quad (9)$$

Substitution of Eqs. (6) and (9) into Eq. (8) yields the steady stress tensor

$$s_n = \sigma_0 \begin{pmatrix} 1 + 2(\lambda/\beta)^2 & \lambda/\beta & 0 \\ \lambda/\beta & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (10)$$

The xy - and yz -components give the shearing stresses constraining the simple shearing flow Eq. (6), and μ defined by

$$\mu = \sigma_{xy}/\lambda = \sigma_0/\beta \quad (11)$$

represents the Newtonian viscosity coefficient. σ_0 is the instantaneous elastic modulus (rigidity) of our network, and

$$\tau = 1/\beta \quad (12)$$

has the meaning of the so-called relaxation time.

Purely viscous liquids may have no normal components of stress but only the isotropic hydrostatic pressure in simple shearing flow. In our system, however, there exists an additional normal component of stress, $2\sigma_0(\lambda/\beta)^2$, in the flow-direction. This quantity which is

of second order with respect to the flow parameter, λ , is one of the cross effects in the stress-strain relation, and is always neglected in the classical linear theory of (visco-) elasticity. But it is this term which plays an important role in the normal stress effect, as will be shown in the following sections.

Through an analogous procedure to that of the previous paper²⁾ we can easily get an expression of the stress tensor without appealing to the assuming of Gaussian chain and of the constant chain-breakage coefficient. In the case of small values of λ , the stress tensor may be expanded in powers of λ as

$$\sigma_{tt} = \sum_{n=0}^{\infty} \sigma_{tt}^{(2n)} \lambda^{2n}, \quad (t=x, y, z), \quad (13a)$$

$$\sigma_{xy} = \sigma_{yz} = \sum_{n=0}^{\infty} \sigma_{xy}^{(2n+1)} \lambda^{2n+1}, \quad (13b)$$

$$\sigma_{zz} = \sigma_{zz} = 0, \quad (s=x, y). \quad (13c)$$

The details of calculation¹⁾ and the final expression of $\sigma_{zz}^{(m)}$ for $m=0\sim 3$ are given in Appendix. σ_{yy} is generally not equal to σ_{zz} . σ_{xy} may have the terms of higher powers of λ than the first, which correspond to the so-called non-Newtonian (or, structural) viscosity:

$$\mu = \sigma_{xy} / \dot{\lambda} = \sum_{n=0}^{\infty} \mu^{(2n)} \lambda^{2n}, \quad (14)$$

$$\mu^{(2n)} = \sigma_{xy}^{(2n+1)}. \quad (15)$$

Eq. (13c) hold for any value of λ in our model.

If the higher derivatives of $\beta(r, N)$ and $\phi(r, N)$ with respect to r are sufficiently small, the following relation is obtained (cf. Appendix):

$$\frac{|\sigma_{yy}^{(2)} - \sigma_{zz}^{(2)}|}{\sigma_{yy}^{(0)}} \leq \frac{1}{5} \frac{|\mu^{(2)}|}{\mu^{(0)}}. \quad (16)$$

This means that the "order" of the anisotropy of normal stress components should be smaller than the "order" of the structural viscosity.

§ 3. Pressure Distribution in Circular Motion of Liquid. (I)

By application of the expressions for the stress tensor obtained in the last section and of Euler equations (4) or (5) we can calculate the pressure distribution in the circular motion of liquid. In this section the simplest stress tensor, Eq. (10), is adopted for three types of instruments. The more general

stress tensor, Eq. (14), will be treated only for the cone-plate instrument in the next section.

A. Coaxial cylinder instrument

Consider the motion of liquid put into the gap between two coaxial cylindrical surfaces (their radii are a and b ($a > b$), respectively), both of which rotate around their common axis with angular velocities Ω_A and Ω_B ($\Delta\Omega = \Omega_A - \Omega_B$), respectively. Using cylindrical coordinates (r, φ, z) , let us consider a steady flow in φ -direction with angular velocity $\omega = \omega(r)$ and neglect the end effect for simplicity's sake. The velocity gradient,

$$\lambda = r(d\omega/dr) \quad (17)$$

is in the r -direction. In this system the gravitational and the centrifugal force act on the bulk of the liquid, and since we assume that the z -axis is in the vertical direction, the body force is written as

$$(R, \theta, Z) = (\rho r \omega^2, 0, -\rho g) \quad (18)$$

where ρ is the density of the liquid.

P and λ are obtained as the functions of coordinates by solving the Euler equations with Eq. (17) and the stress tensor which is analogous to Eq. (10). That is,

$$\lambda = 2A/r^2, \quad (19)$$

$$P = P' - 2A^2(\sigma_0/\beta^2)(1/r^4). \quad (20)$$

Where P' is a part of the hydrostatic pressure arising from the body force,

$$P' = \rho \left\{ \frac{A^2}{2} \frac{1}{r^2} + AB \log r - \frac{B^2}{2} r^2 \right\} + \rho g z + P_0, \quad (21)$$

and constants A and B are given in the forms

$$A = (\Omega_A - \Omega_B) \frac{a^2 b^2}{a^2 - b^2} \quad (22)$$

and

$$B = \frac{a^2 \Omega_A - b^2 \Omega_B}{a^2 - b^2}. \quad (23)$$

In Eq. (20), the second term $2A^2\sigma_0/\beta^2 r^4$ gives the contribution from the additional normal stress component. If the network formation is remarkable, P' may be neglected in the expression of P .

Substitution of P into Eq. (7) gives the distribution of stress in the velocity field. As the actually measurable pressures are the minus signes of the stresses, we obtain

$$P_z = P_r = P_0 + 2A^2(\sigma_0/\beta^2)(1/r^4) \quad (24)$$

and

$$P_\varphi = P_0 - 6A^2(\sigma_0/\beta^2)(1/r^4). \quad (25)$$

Eq. (24) suggest that the vertical cross-section of the free surface of the liquid passing through the rotational axis is expressed as $z=c/r^4$. This is just the tendencies of the experimental results.

Eqs. (24) and (25) show that the nearer is the location of the bluk of the liquid to the rotational axis, the larger are the pressures in the r - and z -directions, and the smaller in the φ -direction. Let us consider a doughnut-shaped section of the liquid along a flow line. Eqs. (7) and (10) imply that there exists a tension along the circular axis of this doughnut-shaped section. Then this bulk may squeeze the inner part of the liquid as the circularly stretched rubber loop. This effect results in the pressure distributions, Eqs. (24) and (25), and then, in the normal stress effect.

B. Parallel plate instrument.

The similar procedure determines the pressure distribution in the parallel plate instrument. The velocity gradient

$$\lambda = r(d\omega/dz) = r(\Delta\Omega/h) \quad (26)$$

is in the z -direction, where h is the distance between two horizontal circular plates which rotate around the vertical axis with angular velocities, Ω and $\Omega + \Delta\Omega$, respectively. If the gravitational and the centrifugal forces are neglected, we arrive at the pressure distribution

$$P_r = P_z = P_0 - (\sigma_0/\beta^2)(\Delta\Omega/h)^2 r^2, \quad (27)$$

$$P_\varphi = P_0 - 3(\sigma_0/\beta^2)(\Delta\Omega/h)^2 r^2. \quad (28)$$

Eq. (27) suggests that the vertical component of pressure, which can be measured by capillary tube, decreases parabolically with increasing distance from the rotating axis. This tendency is not strictly the one observed by the experiments. Greensmith and Rivlin's data of 6% decalin solution of polyisobutylene,¹¹⁾ and Kotaka, Tamura and Kurata's data for aqueous solutions Na-carboxymethylcellulose (Na-CMC) with several amounts of NaOH¹²⁾ show clearly the departures from parabolic pressure-distribution. This may be due to "non-linearity" of visco-elastic properties of these systems, that is, due to the velocity gradient dependences of the elastic

modulus, σ_0 , and of the relaxation time, τ .

C. Cone and plate instrument (Involved cone-cone arrangement).

It is convenient to make use of the polar coordinate, (r, θ, φ) , for the conical surface (cone-plate and cone-cone) instruments. Two conical surfaces are characterized by $\theta = \alpha$ and $\theta = \beta$ ($\alpha - \beta = \delta > 0$) and rotate with angular velocities, $\Omega + \Delta\Omega$ and Ω , respectively. With sufficiently small value of δ , the liquid flows laminarly in the φ -direction with the velocity gradient

$$\lambda = d\omega(\theta)/d\theta \quad (29)$$

in the θ -direction. Eq. (5c) leads to

$$\lambda = A/\sin^2 \theta, \quad (30)$$

where

$$A = -\Delta\Omega/(\cot \alpha - \cot \beta). \quad (31)$$

In what follows, for the convenience of calculation, we assume that both α and β are nearly equal to 90° . The velocity gradient in this situation

$$\begin{aligned} \lambda &= \frac{A}{\sin^2 \alpha} [1 - 2 \cot \alpha \cdot (\theta - \alpha) \\ &\quad + (1 + 3 \cot^2 \alpha)(\theta - \alpha)^2 + \dots] \\ &\simeq A/\sin^2 \alpha = \Delta\Omega/\delta \end{aligned} \quad (32)$$

is independent of location of the point being considered. The cone-plate instrument with a narrow gap satisfies this condition. The pressure distribution may be obtained as

$$P_r = P_\theta = P_0 - 2(\sigma_0/\beta^2)(\Delta\Omega/\delta)^2 \log r, \quad (33)$$

$$\begin{aligned} P_\varphi &= P_0 - 2(\sigma_0/\beta^2)(\Delta\Omega/\delta)^2 \log r \\ &\quad - 2(\sigma_0/\beta^2)(\Delta\Omega/\delta)^2. \end{aligned} \quad (34)$$

with the neglect of body forces. The θ -component of the pressure has the logarithmic dependence on distance from the axis. This is consistent with the experimental results carried out by several authors. However, λ vs. $(-\partial P_\theta/\partial \log r)$ relations obtained by experiments show more or less departure from the parabolic dependence. In the next section, we shall consider this point in more detail.

§ 4. Pressure Distribution in Circular Motion of Liquid. (II)

A part of this section is concerned with the more general liquids inserted into the cone-plate instrument. The stress tensor for laminar rotating motion in this instrument

may have such a form in the polar coordinate that (cf. Eq. (13))

$$\mathbf{s} = \begin{pmatrix} \sigma_{rr}'(\lambda) & 0 & 0 \\ 0 & \sigma_{\theta\theta}'(\lambda) & \sigma_{\theta\varphi}'(\lambda) \\ 0 & \sigma_{\varphi\theta}'(\lambda) & \sigma_{\varphi\varphi}'(\lambda) \end{pmatrix} + P\mathbf{1}, \quad (35)$$

with

$$\sigma_{\theta\varphi}'(\lambda) = \sigma_{\varphi\theta}'(\lambda). \quad (36)$$

Substitution of Eq. (35) into Eq. (5c) gives the equation

$$(\partial\sigma_{\theta\varphi}/\partial\lambda)(d\lambda/d\theta) = -2 \cot \theta \cdot \sigma_{\theta\varphi}. \quad (37)$$

This implies the constancy of λ' in the cone-plate instrument in which $\theta \simeq 90^\circ$, $\cot \theta \simeq 0$:

$$\lambda = \Delta Q / \delta = \text{const.} \quad (38)$$

Eqs. (5a), (5b) and (38) determine the hydrostatic pressure, P . With neglect of the body forces, normal components of the pressure,

$$P_t = -\sigma_{tt}, \quad (t=r, \theta, \varphi)$$

may be written as

$$P_t = P_0(\theta) + (2\sigma_{rr}' - \sigma_{\theta\theta}' - \sigma_{\varphi\varphi}') \log r - \sigma_{tt}', \quad (t=r, \theta, \varphi). \quad (39)$$

Then, we have

$$(\partial P_t / \partial \log r) = 2\sigma_{rr}' - \sigma_{\theta\theta}' - \sigma_{\varphi\varphi}' = -C = \text{const.}, \quad (40)$$

$$P_r - P_\theta = \sigma_{\theta\theta}' - \sigma_{rr}', \quad (41)$$

$$P_r - P_\varphi = \sigma_{\varphi\varphi}' - \sigma_{rr}'. \quad (42)$$

Eq. (40) suggests the logarithmic r -dependence of the normal components of the pressure, which has just been observed by Roberts, Rhilippoff, and others. Eqs. (1) and (2), the results of Robert's experiment,⁵⁾ are considered to be the special case of $\sigma_{\theta\theta}' = \sigma_{rr}'$.

Eq. (16) may be expected for the network model in which $\beta(r, N)$ and $\phi(r, N)$ are not so singular function of r . This implies that the difference $|P_r - P_\theta|$ may be comparatively small even if the non-Newtonian flow is observed, at least in the range of small λ -value. What may happen for large λ -value? With Gaussian chains and constant chain-breakage coefficient, there exists only the additional tension $(2\sigma_0/\beta^2)\lambda^2$ in the normal stress component of the flow-direction. If $\beta(r, N)$ increases with r , i.e., the probability of breakage of junctions increases with stretching of chains, the effective number and the average tension of chains may be smaller than those in the case of constant β for the same of

stress. Especially, $\sigma_{\theta\theta} - \sigma_{rr}$, which is zero at $\lambda=0$, may remain in the vicinity of zero although σ_{tt} itself apparently deviates from those of the ideal case. Similarly, an effect of non-Gaussian behavior of constituent chains may arise. Denoting the effective instantaneous elastic modulus by $\kappa_e(\lambda) = \langle \sigma_0 \rangle$ and the effective relaxation time by $\tau_e(\lambda) = 1/\langle \beta \rangle$, we may write approximately the stress tensor for simple shearing flow, Eq. (16), in the form

$$\mathbf{s} = \kappa_e \begin{pmatrix} 1 + 2\tau_e^2 \lambda^2 & \tau_e \lambda & 0 \\ \tau_e \lambda & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} + P\mathbf{1}. \quad (43)$$

This stress tensor gives an explanation of Robert's experimental results,³⁾ Eqs. (1)~(3).

λ -dependence of the additional normal tension, $\Delta\sigma = 2\kappa_e \tau_e^2 \lambda^2$, can be obtained directly from the measurement of the normal stress effect in any instrument. On the other hand, measurement of the structural viscosity gives the $\mu = \kappa_e \tau_e$ vs. λ relation. Then, we can separately obtain the λ -dependence of the effective elastic modulus $\kappa_e(\lambda)$ and of the effective relaxation time $\tau_e(\lambda)$. This is an important feature of the observation of the normal stress effect in the rheological considerations of elastico-viscous liquids.

In a suitable range of λ -value, it has been seen experimentally that $\Delta\sigma$ and μ depend on λ in the power forms

$$\Delta\sigma = A\lambda^\alpha, \quad (44)$$

$$\mu = B\lambda^{-\beta}. \quad (45)$$

This implies in this range of λ -value the tendencies

$$\kappa_e(\lambda) = \kappa_0 \lambda^\delta, \quad (46)$$

$$\tau_e(\lambda) = \tau_0 \lambda^{-\varepsilon}. \quad (47)$$

In Fig. 2 is shown the relation between $[\alpha, \beta]$ and $[\delta, \varepsilon]$. τ_e should decrease with λ , and the degree of the orientation of the internal mechanism, which is expressed by $\xi = \tau_e \lambda$, should increase with λ . Then, it is necessary that $0 < \varepsilon < 1$. In our network model δ expresses the departure from the Gaussian nature of chains, and because of the nature of real chains, it is supposed that $\delta > 0$. Observable set of $[\alpha, \beta]$ would be in the domain MABN in Fig. 2. In this figure, the full circles represent the experimental results for aqueous solutions of Na-carboxylmethyl-

cellulose (Na-CMC), the deltas for aqueous solutions of methylcellulose (MC) and the crosses for decalin solutions of polystyrene by Kurata, Kotaka and Tamura.^{13)*} The open circle corresponds to the decalin solution of polyisobutylene by Garner, Nissan and Wood,¹³⁾ and Mooney.¹⁶⁾ These plots suggest that in the case of random coiled linear

molecules such as polystyrene and polyisobutylene in decalin, polymer chains are fairly approximately represented by the Gaussian chains, and non-Newtonian flow of these system is chiefly due to the λ -dependence of the relaxation time. On the contrary, chains of cellulose derivatives and polyelectrolytes show remarkable departure from the Gaussian character. This is an expected result.

§ 5. General Remarks

A. Assumption of simple circular motion.

Pressure distributions in elasto-viscous liquids were treated for simple circular motions of three types. In our calculations it was assumed that the flow lines of liquid-motion were concentric circles around the rotational axis. This assumption is actually not the case for the parallel plate instrument and the conical surface instrument, when we take the effect of body forces into consideration. For example, let us consider the parallel plate instrument. The body force in this case, too, is given by Eq. (18). The angular velocity is the function of z given by

$$\omega(z) = \Omega_0 + (\Delta\Omega/h)z \quad (48)$$

with the velocity gradient, Eq. (26), in the z -direction. With Eqs. (18), (26) and (48) and suitable expression of stress tensor, Euler equations (4) can not be solved with respect to P ; P is not a total differential of r and z . This implies that the assumption of the simple circular motion conflicts with the actual flow pattern under the influence of the body force, Eq. (18). Consider a vertical cylindrical section of the liquid in this instrument. The gravitational force homogeneously acts in parallel to the cylindrical axis and gives no moment of force. On the other hand, the centrifugal force is in the r -direction orthogonal to the cylindrical axis, and its magnitude is a function of z , because of non-uniformity of the angular velocity, Eq. (48). Then there exists a moment of force in the φ -direction. This moment leads to an additional convection of the liquid in the $r\theta$ -plane. Hence a bulk of the liquid will make a complex helical motion. The neglect of body forces, then, amounts to the assumption of the simple circular motion at least for the parallel plate instrument.

For the cone-cone instrument, furthermore, this assumption does not hold even if body

forces are neglected. Substituting the expression of the velocity gradient, Eq. (30), Euler equations (5) may not lead to the consistent solution of P . In this case, the balancing of the stress as a whole is impossible, and then, a convective motion of the liquid may happen. However, in the case of the cone-plate instrument, in which $\theta \simeq 90^\circ$, the dependence of λ on θ may be neglected, and the liquid is in the simple circular motion under the condition of no body force. Our calculation has a meaning only in this case.

B. Symmetry and asymmetry of deformation.

The essential point of the normal stress effects, either Poynting or Weissenberg effects, lies in the existence of the additional normal tension which is of the second order with respect to the magnitude of the deformation or velocity gradient in the deformation or flow-direction. An inequality of the normal stress components of such direction and the gradient-direction is important in the interpretations of several results on the anisotropy of the normal pressure. This property of the stress tensor is clearly due to the asymmetry of the deformation tensor, Eq. (6).

In the explanation of the normal stress effect, Rivlin has symmetrized the deformation tensor, as has been done in the classical theory of elasticity.* His symmetrized tensor

$$e_s = \begin{pmatrix} 1 & \lambda t/2 & 0 \\ \lambda t/2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (49)$$

leads to the stress tensor such as

$$s_s = \begin{pmatrix} \Psi \lambda^2/2 & \Theta \lambda & 0 \\ \Theta \lambda & \Psi \lambda^2/2 & 0 \\ 0 & 0 & 0 \end{pmatrix} + P\mathbf{1}, \quad (50)$$

which has the discrepancy from that experimentally obtained, Eqs. (1) and (2).

The symmetrization of deformation is accompanied with the neglect of second order quantities of deformation. This procedure is

* In the recent paper,¹⁵⁾ Rivlin has developed the phenomenological theory of elasticity in which the general asymmetrical deformation is correctly treated. He has obtained the stress tensor which is essentially equivalent to Eq. (10) for the simple shearing deformation with the displacement gradient, λ , instead of the velocity gradient.

permitted in the classical linear theories of elasticity and visco-elasticity in which only small deformations are treated. However, this symmetrization may, of course, be impossible in the treatment of second order effects such as the normal stress effects.

The symmetric deformation, Eq. (49), has the strain ellipsoid one of whose principal axes bisects the first quarter of the xy -plane. On the other hand, in the case of asymmetric stress tensor, Eq. (6), the x -axis has an acute angle with a principal axis of the strain ellipsoid in the first quarter of the xy -plane. This implies that the extinction angle, χ , is less than 45° in the experiment of flow birefringence. χ is dependent on the velocity gradient such as

$$2 \cot 2\chi = \lambda \tau_e(\lambda) \quad (51)$$

for our network model. $\lambda \tau_e(\lambda)$ may be obtained for any λ -value by measurement of the normal stress effect and of the viscosity coefficient, as was shown in the last section. Philippoff showed a good agreement between the extinction angle obtained by a direct measurement of the flow birefringence and that obtained by measuring the mechanical properties using Eq. (51).⁹⁾ This fact suggests that the asymmetry of deformation is important in our system.

§ 6. Summary

The normal stress effect of elastico-viscous liquids (Weissenberg effect) was treated adopting the weakly coupled rubber-like network model. It was shown that the normal stress of these systems is no longer isotropic for a stationary simple shearing flow. Although normal components of the stress are in general different from each other in magnitude, those along the directions orthogonal to the flow-direction are almost isotropic. A remarkable additional tension must be applied in the flow-direction in order to compel the system to the said flow. This tension leads to the non-uniform distribution of the normal pressure in some concentric circular motion of the liquid. These distributions were obtained for three types of experimental arrangements with coaxial cylinders, parallel plates and cone-plate, respectively. The results of our theory are at least qualitatively consistent with that obtained by ex-

periments, although the treatment is limited in the rather simple case, that is, in the simple concentric circular motions. By the observations of the normal stress effect and the viscosity coefficient, we can determine the effective elastic modulus (rigidity) and the effective relaxation time at any value of velocity gradient. This may have an important role in the study of the rheological behavior of such systems. For example, it can be possible to separate the non-linearity of visco-elastic properties into that of conservative elastic part and that of dissipative relaxational part. The similar separation may be made for the well-known molecular weight dependence of visco-elastic parameters. Especially, it will be expected that in the analysis of the law of 3.4th power for molecular weight dependence of the bulk viscosity of amorphous polymers, the normal stress effect will give an important contribution.*

Acknowledgement

The author wishes to express his sincere thanks to Professor T. Yamamoto and Professor M. Kurata for the continual encouragement and the guidance throughout the course of the present study. They have kindly inspected and revised the manuscript, too. He is also obliged to Professor T. Nakagawa of Tokyo University who suggested the problem, Professor H. Fujita and Dr. Y. Ikeda for their kindly lending of reference papers, and Dr. E. Teramoto and the members of our laboratory (Quantum Chemistry Lab., Dept. of Chemistry, Kyoto Univ.), of Research Group of High Polymer in Kyoto and of Kobayasi Institute of Physical Research, Tokyo, for their fruitful discussions. His thanks are also due to Miss M. Matsuda for the preparation of the manuscript. The present investigation was supported partly by the Scientific Research Grant of the Ministry of Education.

Appendix

In the first paper¹⁾ of this series, we have derived the stress tensor, s , of the weakly coupled network structure for any strain tensor, e . In the case of incompressible substances, the stress tensor is given by

$$s = \Sigma_N \iiint (h\mathbf{h}) \left(\frac{1}{r} \frac{d\phi}{dr} \right)_{r=h_1} F(\mathbf{h}, N, t) d\mathbf{h} + P\mathbf{1}, \quad (\text{A.1})$$

where $\phi(r, N)$ is the free energy of a chain having the end-to-end distance, r . The chain-distribution function, $F(\mathbf{h}, N, t)$, satisfies the equation

$$\begin{aligned} F(\mathbf{h}, N, t) = & F_0(\mathbf{e}^{-1}(t) \cdot \mathbf{h}, N) \exp \left[- \int_0^t \beta(\mathbf{e}(t') \cdot \mathbf{e}^{-1}(t) \cdot \mathbf{h}, N) dt' \right] \\ & + \int_0^t G(\mathbf{e}(t') \cdot \mathbf{e}^{-1}(t) \cdot \mathbf{h}, N, t') \exp \left[- \int_{t'}^t \beta(\mathbf{e}(t'') \cdot \mathbf{e}^{-1}(t) \cdot \mathbf{h}, N) dt'' \right] dt', \end{aligned} \quad (\text{A.2})$$

where $G(\mathbf{h}, N, t)$ is the chain-reformation function and $\beta(\mathbf{h}, N)$ is the chain-breakage coefficient.

In our case the strain tensor $\mathbf{e}(t)$ has the form

$$\mathbf{e}(t) = \begin{pmatrix} 1 & \lambda t & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (\text{A.3})$$

Substitution of Eq. (A.3) into Eq. (A.2) gives the following stationary chain-distribution function

$$F(\xi, \eta > 0, \zeta; N) = \frac{1}{\lambda \eta} \int_{-\infty}^{\xi} G(\xi', \eta, \zeta; N) \exp \left[- \frac{1}{\lambda \eta} \int_{-\xi}^{\xi} \beta(\xi'', \eta, \zeta; N) d\xi'' \right] d\xi', \quad (\text{A.4a})$$

* Such measurement of the molecular weight dependence of normal stresses are now in progress by Kotaka, Kurata, Sakamoto and Tamura for polystyrene solutions as an example.

$$F(\xi, \eta < 0, \zeta; N) = \frac{1}{\lambda|\eta|} \int_{-\infty}^{-\xi} G(\xi', |\eta|, \zeta; N) \exp \left[-\frac{1}{\lambda|\eta|} \int_{\xi'}^{-\xi} \beta(\xi'', |\eta|, \zeta; N) d\xi'' \right] d\xi'. \quad (\text{A4b})$$

Making use of the similar procedure to that of the second paper²⁾ of this series, we can obtain the stress components, that is,

$$\sigma_{xx} = 2\Sigma_N \iiint_{\Omega''} \xi^2 G(|\mathbf{h}|, N) [K_2^+ + K_2^-] d\mathbf{h} + P, \quad (\text{A.5a})$$

$$\sigma_{xt} = \sigma_{tx} = 2\Sigma_N \iiint_{\Omega''} \xi \tau G(|\mathbf{h}|, N) [K_1^+ + K_1^-] d\mathbf{h} \quad (\text{A.5b})$$

and

$$\sigma_{st} = \sigma_{ts} = 2\Sigma_N \iiint_{\Omega''} \sigma \tau G(|\mathbf{h}|, N) [K_0^+ + K_0^-] d\mathbf{h} + P\delta_{st}, \quad (\text{A.5c})$$

($s, t = x, y, z; \sigma, \tau = \eta, \zeta$).

In this derivation, it is assumed that $\beta(\mathbf{h}, N)$ and $G(\mathbf{h}, N, t)$ are spherically symmetric. Ω'' denotes the quartered space, $\xi > 0$ and $\eta > 0$. $K_n^\pm$ is defined such as

$$K_n^\pm = \frac{\xi}{\lambda\eta} \int_{\pm 1}^{\infty} \theta^n \left(\frac{1}{r} \frac{d\phi}{dr} \right)_{(\theta)} \exp \left[-\frac{\xi}{\lambda\eta} \int_{\pm 1}^{\infty} \beta(\xi\theta', \eta, \zeta; N) d\theta' \right] d\theta. \quad (\text{A.6})$$

where $(1/r)(d\phi/dr)_{(\theta)}$ is the abbreviation

$$\left(\frac{1}{r} \frac{d\phi}{dr} \right)_{(\theta)} = \left(\frac{1}{r} \frac{d\phi}{dr} \right)_{r=\sqrt{\theta^2\xi^2+\eta^2+\zeta^2}}. \quad (\text{A.7})$$

Because of the spherical symmetry of $G(\mathbf{h}, N)$, $\beta(\mathbf{h}, N)$ and $\phi(\mathbf{h}, N)$, $K_n^\pm$ has planar symmetry with respect to the xy -plane. Hence we have

$$\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = 0. \quad (\text{A.8})$$

No more reduction of these equations can be made for general functional forms of $\beta(r, N)$ and $\phi(r, N)$.

If the chains are Gaussian and $\beta(r, N)$ is independent of r and N , i.e.,

$$\phi(r, N) = (3kT/2)(r^2/Na^2) \quad (\text{A.9})$$

and

$$\beta(r, N) = \beta = \text{const.}, \quad (\text{A.10})$$

$K_n^\pm$ may be read

$$K_0^\pm = \frac{3kT}{Na^2} \frac{1}{\beta}, \quad (\text{A.11})$$

$$K_1^\pm = \frac{3kT}{Na^2} \frac{1}{\beta} \left(\frac{\lambda}{\beta} \frac{\eta}{\xi} \right) \left[1 \pm \frac{\beta}{\lambda} \frac{\xi}{\eta} \right], \quad (\text{A.12})$$

$$K_2^\pm = \frac{3kT}{Na^2} \frac{1}{\beta} \left[1 \pm 2 \frac{\lambda}{\beta} \frac{\eta}{\xi} + 2 \left(\frac{\lambda}{\beta} \frac{\eta}{\xi} \right)^2 \right]. \quad (\text{A.13})$$

Introducing of the instantaneous elastic modulus, σ_0 ,

$$\sigma_0 = \frac{kT}{a^2} \frac{1}{\beta} \Sigma_N \frac{1}{N} \iiint \mathbf{h}^2 G(\mathbf{h}, N) d\mathbf{h}, \quad (\text{A.12})$$

we can reduce the stress tensor, Eq. (A.5), to the form described in Eq. (10).

For sufficiently small λ -value, the stress tensor is expanded in powers of λ , as has been done in the calculation of the viscosity coefficients in the previous paper²⁾:

$$\sigma_{tt} = \sum_{n=0}^{\infty} \sigma_{tt}^{(2n)} \lambda^{2n}, \quad (\text{A.13})$$

$$\sigma_{xy} = \sigma_{yx} = \sum_{n=0}^{\infty} \sigma_{xy}^{(2n+1)} \lambda^{2n+1}. \quad (\text{A.14})$$

Simple but lengthy calculation determines the expansion coefficients as follows:

Define the differential operator

$$D^n = \left(\frac{1}{r} \frac{d}{dr} \right)^n, \quad (\text{A.15})$$

to give

$$\sigma_{zz}^{(0)} = \sigma_{yy}^{(0)} = \sigma_{xx}^{(0)} = \frac{4}{3} \pi \Sigma_N \int r^4 \frac{G(r, N)}{\beta(r, N)} D^1 \phi \, dr, \quad (\text{A.16})$$

$$\begin{aligned} \sigma_{xx}^{(2)} = & \frac{8}{3} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^3(r, N)} D^1 \phi \, dr + \frac{4}{15} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^3(r, N)} \left[6D^2 \phi - 7D^1 \phi \left(\frac{D^1 \beta}{\beta} \right) \right] dr \\ & + \frac{4}{35} \pi \Sigma_N \int r^8 \frac{G(r, N)}{\beta^3(r, N)} \left[2D^3 \phi - 3D^2 \phi \left(\frac{D^1 \beta}{\beta} \right) - D^1 \phi \left\{ \left(\frac{D^2 \beta}{\beta} \right) - \left(\frac{D^1 \beta}{\beta} \right)^2 \right\} \right] dr, \end{aligned} \quad (\text{A.17a})$$

$$\begin{aligned} \sigma_{yy}^{(2)} = & \frac{4}{5} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^3(r, N)} \left[2D^2 \phi - D^1 \phi \left(\frac{D^1 \beta}{\beta} \right) \right] dr \\ & + \frac{4}{35} \pi \Sigma_N \int r^8 \frac{G(r, N)}{\beta^3(r, N)} \left[2D^3 \phi - 3D^2 \phi \left(\frac{D^1 \beta}{\beta} \right) - D^1 \phi \left\{ \left(\frac{D^2 \beta}{\beta} \right) - \left(\frac{D^1 \beta}{\beta} \right)^2 \right\} \right] dr, \end{aligned} \quad (\text{A.17b})$$

$$\sigma_{zz}^{(2)} = \frac{1}{3} \sigma_{yy}^{(2)}, \quad (\text{A.17c})$$

$$\sigma_{xy}^{(1)} = \frac{4}{3} \pi \Sigma_N \int r^4 \frac{G(r, N)}{\beta^2(r, N)} D^1 \phi \, dr + \frac{4}{15} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^2(r, N)} \left[D^2 \phi - D^1 \phi \left(\frac{D^1 \beta}{\beta} \right) \right] dr, \quad (\text{A.18})$$

$$\begin{aligned} \sigma_{xy}^{(3)} = & \frac{8}{5} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^4(r, N)} \left[3D^2 \phi - 2D^1 \phi \left(\frac{D^1 \beta}{\beta} \right) \right] dr \\ & + \frac{4}{35} \pi \Sigma_N \int r^8 \frac{G(r, N)}{\beta^4(r, N)} \left[24D^3 \phi - 28D^2 \phi \left(\frac{D^1 \beta}{\beta} \right) - D^1 \phi \left\{ 7 \left(\frac{D^2 \beta}{\beta} \right) - 25 \left(\frac{D^1 \beta}{\beta} \right)^2 \right\} \right] dr \\ & + \frac{4}{105} \pi \Sigma_N \int r^{10} \frac{G(r, N)}{\beta^4(r, N)} \left[6D^4 \phi - 12D^3 \phi \left(\frac{D^1 \beta}{\beta} \right) - D^2 \phi \left\{ \left(\frac{D^2 \beta}{\beta} \right) - 15 \left(\frac{D^1 \beta}{\beta} \right)^2 \right\} \right. \\ & \left. - D^1 \phi \left\{ \left(\frac{D^3 \beta}{\beta} \right) - 10 \left(\frac{D^2 \beta}{\beta} \right) \left(\frac{D^1 \beta}{\beta} \right) + 15 \left(\frac{D^1 \beta}{\beta} \right)^3 \right\} \right] dr, \end{aligned} \quad (\text{A.19})$$

Consider the difference $\sigma_{yy} - \sigma_{zz}$:

$$\sigma_{yy}^{(0)} - \sigma_{zz}^{(0)} = 0, \quad (\text{A.20})$$

$$\begin{aligned} \sigma_{yy}^{(2)} - \sigma_{zz}^{(2)} = & \frac{8}{15} \pi \Sigma_N \int r^6 \frac{G(r, N)}{\beta^3(r, N)} \left[2D^2 \phi - D^1 \phi \left(\frac{D^1 \beta}{\beta} \right) \right] dr \\ & + \frac{8}{105} \pi \Sigma_N \int r^8 \frac{G(r, N)}{\beta^3(r, N)} \left[2D^3 \phi - 3D^2 \phi \left(\frac{D^1 \beta}{\beta} \right) - D^1 \phi \left\{ \left(\frac{D^2 \beta}{\beta} \right) - \left(\frac{D^1 \beta}{\beta} \right)^2 \right\} \right] dr, \end{aligned} \quad (\text{A.21})$$

The viscosity coefficient, μ , is given by

$$\mu = \sigma_{xy} / \dot{\lambda} = \sum_{n=0}^{\infty} \mu^{(2n)} \dot{\lambda}^{2n} \quad (\text{A.22})$$

where the expansion coefficients are

$$\mu^{(2n)} = \sigma_{xy}^{(2n+1)} . \quad (\text{A.23})$$

If $\beta(r, N)$ and $\phi(r, N)$ do not so sharply change with r , comparison of Eqs. (A.18), (A.19) and (A.20), (A.21) leads to the relation

$$\frac{|\sigma_{yy}^{(2)} - \sigma_{zz}^{(2)}|}{\sigma_{yy}^{(0)}} \leq \frac{1}{5} \frac{|\mu^{(2)}|}{\mu^{(0)}} . \quad (\text{A.24})$$

Disturbance Phenomena in Probe Measurement of Ionized Gases

By Takayoshi OKUDA and Kenzo YAMAMOTO

Faculty of Engineering, University of Nagoya, Nagoya

(Received June 20, 1958)

This paper is concerned with disturbance phenomena occurring when a probe is immersed in plasma.

There are two types of disturbance, i.e., one independent of probe potential and one which depends upon it. The former (inherent) disturbance has three effects which are classified: Asymmetrical effect, formation effect of transition region, and the scattering effect. The latter (incidental) depends on either the negative probe or the positive probe. In the negative probe, penetration of ion sheath into surrounding plasma is characteristic. In the positive probe, there is an unexpected change of electron current, as a result of drainage of electron, which is observed with rise of positive probe voltage.

The mechanism of collection of ion and electron on probe is also explained in terms of these disturbance effects.

§ 1. Introduction

A complicated situation arises when, as is usually encountered in the laboratory work, a probe of finite dimension is immersed in a plasma having a finite extent and density, resulting in disturbance. In reality, the disturbance has a marked influence on determination of plasma density made by ordinary probe method, as already described in a previous paper¹⁾.

Here, for the purpose of insuring accuracy of measurement, it is necessary to have complete knowledge of the conditions resulting from insertion of probe in laboratory plasma.

Since disturbance may be responsible for formation of a disturbed region spreading extensively into plasma and controlling density of charged particle near the probe⁽²⁾, the purpose of this paper is to clarify disturbance phenomena and to explain how it affects collection of charged particle.

Finally, we elucidate causes of error and improve reliability of measurement. Also, the conclusions obtained in this study offer helpful information on interesting problems in practical use of the third electrode, viz., grid electrode in discharge tube or extracting electrode in various ion sources.

§ 2. Experimental Procedures

All experimental discharge tubes used in this work are sealed-off tubes, made of hard glass, having an oxide coated cathode, a Ni disc anode and Mo probes. Gases of Ne and

Ar are used. Since commercial Ne and Ar are both only 99.9% pure, they are purified by means of Ca getter.

Ultimate pressure of vacuum system is of the order of 10^{-7} mm Hg and gas pressure used ranges from 10^{-3} to 10 mm Hg. The discharge currents are below 1.0 A and tube voltages are several tens volts. Structures, dimensions and materials of peculiar probes are described in detail in Section 3.

§ 3. Experimental Results and its Consideration

A. General view of disturbance

(1) Visual observation of disturbance near a probe

When a probe with floating potential is immersed in a plasma, the outline of an ion sheath forming around the probe is indistinct and in the space surrounding the ion sheath a faintly luminous "disturbed region" appears. Extent of the disturbed region in the direction toward the anode is found to be less than that in the direction toward the cathode, and at the boundary of the disturbed region on the anode side, there is clearly observed a dense plasma having more intense luminosity than that of undisturbed plasma.

At low pressure (below 10^{-3} mm Hg) the local dense plasma is too diffusive to be observed and the distance between probe and the center of the local dense plasma is of the order of several cm. As pressure is raised, such anisotropic appearance becomes more

remarkable and moves nearer the probe.

Fig. 1 shows the disturbed region appearing around a probe held at the floating potential. As shown by the dotted line, the cathode side of the disturbed region expands owing to increase of negative voltage, while the local dense plasma formed on the anode side grows progressively without changing its relative position to the probe.

Fig. 1. Illustrating disturbed region asymmetrically developed around a probe.

As discharge current is reduced, the distance from the probe to the center of local dense plasma decreases slightly, while the extent of the disturbed region on the cathode side increases. Of course, the larger the dimension of probe employed, the greater such an effect.

On the other hand, if the probe potential approaches the plasma potentials by application of probe potential relative to the cathode, ion sheath becomes thinner and at the same time the disturbed region becomes unobservable. Here a somewhat anomalous circumstance is found where the luminosity of the disturbed region on the anode side rather far from probe, as well as that of the local dense plasma, become slightly weaker in comparison with luminosity when the probe potential is negative to plasma. Meanwhile, on the contrary, luminosity of the region close to probe increases. Also, no matter how probe potential is with respect to plasma, the relative position of the local dense plasma is unchanged.

Whenever probe potential is raised until the potential difference between plasma and probe reaches a magnitude corresponding to the first excitation potential of the gas, the layer just covering the probe has a faint glow which is followed by gradual development of a glow similar to the anode glow, indicating occurrence of ionization in electron sheath. As a result, currents flowing into the probe quickly increase, limited by the resistance of probe

circuit. At high pressure, the faint glow can not be distinctly observed, abruptly changing into a glow mode.

(2) Distribution of potential and plasma density in disturbed region.

A movable probe construction is more convenient for measuring potential and plasma density in the disturbed region. In the tube shown in Fig. 2, a disturbing-thick probe can be inserted into or removed from the discharge column normal to the discharge axis, while a measuring-thin probe moves parallel along the discharge axis. In every case, interaction between the thick probe and the thin probe can be regarded as negligible, because the measuring-thin probe is made of small dimension and is always far from the thick probe by several mm.

Fig. 2. Experimental discharge tube with movable probes.

From measurements of potential and plasma density using the thin probe, it is found that the disturbance may exist to a considerable extent even if the pressure is below 10^{-3} mm Hg, where the depletion due to elastic scattering seems to be small compared with that at high pressure, as already mentioned in a previous paper¹⁾.

Consistent with visual observation, the local dense plasma is observed as a maximum of potential and plasma density on anode side of disturbed region. The potential and the plasma density on cathode side of disturbed region change monotonously toward the undisturbed plasma.

By taking the deviation of ion current Δi_p measured at -30 V with respect to the space potential, and taking the deviation of potential ΔV from the undisturbed condition realized by removing the thick probe from the discharge column, we obtain Fig. 3.

Fig. 3 shows distribution of the potential and the ion current as a measure of plasma

density in cases where the thick probe is held at the floating potential.

The way in which the disturbance is connected with discharge current, pressure and probe dimension is obvious from this. As discharge current increases, the local dense plasma develops with increasing distance from the probe, while the extent of cathode side of disturbed region decreases. Those effects,

of course, become more remarkable as the probe radius is enlarged.

To examine how the material of the thick probe affects such disturbance, the same procedure as for Mo probe is carried out with a glass cylinder having the same dimension as Mo probe. The results are identical for both the glass cylinder and the Mo probe.

As potential of probe approaches the space potential, a remarkable change takes place in

Fig. 3. Deviation of ion current and potential from those of the undisturbed case, where the thick probe is absent. The ion current i_{p0} of the undisturbed case is written in figure. (a) 5 mm Hg, (b) 1 mm Hg, (c) $4 \cdot 10^{-3}$ mm Hg of Ar.

Fig. 4. Ion current flowing into thin probes near a thick probe and potential of the thick probe.

Fig. 5. Disturbed region.

Fig. 6. Probe structure for measuring directional collection. (a) Back-to-back probe, (b) Unidirectional probe.

the space around the thick probe. In Fig. 4 the ion current measured by the thin probe is plotted against the potential of the thick probe, showing that the plasma density on anode side of disturbed region decreases, as we observed under visual observation of disturbance near probe.

As shown in Fig. 5, the disturbed region distant from the probe is formed independent of the probe potential. Such a distant disturbed region is called a "transition region". Of course, the disturbed region close to probe is different depending upon whether the potential of probe is negative or positive with respect to plasma.

(3) Directional distribution of ion collection
Here, we investigate how the asymmetrical disturbance is connected with collection of ion on the probe. For this purpose, we prepare the back-to-back plane probes shown in Fig. 6 (a) and a pair of plane probes facing only in the direction, as shown in Fig. 6 (b).

From experiments, it is seen that at extremely low pressures (below 10^{-3} mm Hg) the ion collection on the probe facing the cathode is larger than that on the probe facing the anode, while at high pressure inversed results are obtained. The data obtained by using the tube shown in Figs. 6 (a) and (b), are given in Figs. 7 (a) and (b) respectively.

To obtain the distribution of collection over the whole orientation around probe, we use a parent-daughter probe structure, as shown in Fig. 8, consisting of a (parent) cylindrical probe made of Ni and a plane (daughter) probe made of Mo mounted in an aperture on the surface of the parent probe. This apparatus can be rotated with the help of a magnet.

Measurement of the ion current flowing into the daughter probe at an appropriate negative potential, yields the orientational distribution of the ion collection, provided the parent probe is held at a fixed negative potential. From experiments, we see that asymmetry of distribution of ion collection becomes appreciable as discharge current is raised, as shown in Fig. 9.

We may conclude, therefore, that the asymmetry is closely related to the development of local dense plasma on anode side of disturbed region.

Fig. 10 shows the effect of potential of the parent probe. As the potential of parent probe

(a) Back-to-babk probe is used at 5, 0.25 and 2.5×10^{-3} mm Hg of Ar. (b) Unidirectional probe is used at 5.5×10^{-3} mm Hg of Ar.

Fig. 8. Parent-daughter probe for measurement of directional collection around probe. (a) Scheme of parent-daughter probe, (b) structure of daughter probe.

approaches the space potential, the ion current flowing into the daughter probe increases owing to the increase of plasma density caused by drainage of electron, which we shall discuss later.

The results of experiments may be summarized as follows:

(a) However a probe is held, whether at a negative or positive potential with respect to the plasma, the space surrounding the probe is forced to be disturbed asymmetrically along the direction of discharge axis.

(b) The circumstances of disturbance formed on cathode side of probe and those on anode side are not identical, and their depend-

encies upon such parameters as pressure and discharge current are opposite. A feature of the disturbance appearing on cathode side corresponds to a mechanism of loss of electron by probe acting as an absorbant, while that appearing on anode side corresponds to a mechanism of compensation against loss of electron.

Fig. 9. Directional distribution of ion collection to the daughter probe, when the parent probe is held at the floating potential.

(a) Potential of daughter probe is -65 V with respect to the space. Pressure is 0.5 mm Hg of Ar.

(b) Potential of daughter probe is -45 V with respect to the space. Pressure is 0.04 mm Hg.

Fig. 10 Ion current flowing into a daughter probe measured at -45 V with respect to the space and the potential of the parent probe.

(c) Distant disturbance is not noticeable affected by the material and potential of probe, except that, at positive potential, the plasma density on anode side decreases slightly without changing the relative spatial distribution of density. On the other hand, a close disturbance may be affected by the potential of probe. At negative potential, the penetration of ion sheath occurs, while at positive potential, the increase of density occurs close to electron sheath by virtue of the drainage.

B. Collection of electron and disturbance

Positive probe characteristics are likely to be influenced from some source. It has been seen that in positive column, the electron drift velocity is only a few percent of random velocity of electron³⁾. As a result, if the sheath area is a few percent of the cross section of positive column, the probe current may become comparable to discharge current and, consequently, a distorted characteristic may be obtained, from which one can not estimate plasma quantities of undisturbed plasma.

In addition to this type of disturbance, another one called "drainage" occurs even in conditions in which such distorted character-

istics are not observable.

Now from this standpoint, we examine the behavior of positive probe.

(1) Voltage-current characteristic

Here, we are concerned with slope s in the plot of electron current *vs.* positive probe voltage in log-log scale.

Provided that the collection of electron is limited by sheath area, the value of s depends on plasma density, probe radius and space charge equation applied under that condition. Computation of theoretical value of s can be derived from the assumption that electron current related to sheath area be set equal to electron current based upon space charge equation, as already described in a previous note⁴⁾.

We prepare a concentric cylinder-type tube, as shown in Fig. 11, for the purpose of eliminating asymmetrical disturbance.

Using this tube, we may expect the ratio of cross-section for electrons drifting towards anode to the sheath area to be greater than

that when the ordinary long cylindrical tube is used, and consequently we can expect asymmetrical disturbance to be less than for the long tube.

Experimental results are tabulated in Table I, showing that there is a discrepancy between the measured and the theoretical values. According to our experiment, such discrepancy becomes large as pressure and plasma density are raised.

As a reasonable explanation of the discrepancy, a change in potential of the surrounding plasma relating to probe potential is considered.

To examine this relation, it is better to measure the potential difference ΔV between the space potential deduced from the inflection point of semi-log plot of probe characteristic and a potential where an additional ionization takes place, which means that the sheath voltage reaches a voltage corresponding to the first excitation potential for the gas used. Even under a condition that there is a large discrepancy of slope s , the difference between the first excitation potential and the potential difference ΔV is seen to be quite small. This confirms the fact that the change of plasma potential of the space surrounding probe with change of probe potential, can not be the reason for the discrepancy.

Furthermore, it has already been pointed out in a previous note that there is no ob-

Fig. 11. Concentric-cylinder type tube.

Symbols L and b indicate Langmuir's and b 's law, respectively.

servable relation between collection of electron and sheath radius⁴⁾.

Consequently, as a possible source of such discrepancy, we may consider an anomalous dependency of density of the surrounding space upon positive voltage, which is caused by a drainage of electrons. The drainage appears as a result of penetration of electrons accumulated in electron sheath. Thus, the drainage becomes more pronounced as accumulated charge is increased or as diffusion flow outgoing from the neighboring space of probe is decreased. Consequently it can be seen that as plasma density and gas pressure are increased, slope s must be increased due to the drainage.

Fig. 12. Electron current and sheath radius plotted against positive probe voltage.

Next, we consider the mechanism of collection of electrons on positive probe. When the discharge current is lowered, there is less discrepancy between the measured sheath radius and the theoretical radius. Also, as the discharge current is decreased, there is a closer correspondency between the plot of sheath radius *vs.* positive voltage and the plot of electron current *vs.* positive voltage, as shown in Fig. 12.

Since the drainage decreases as the discharge current or collecting electron current is decreased, a close correspondency between electron current and sheath radius is obtained at low density plasma.

Discrepancy between measured sheath radius and theoretically expected sheath radius can be explained by formation of a penetrating sheath, as in negative probe. Therefore the

measured sheath radius corresponds to a positive voltage which is less than the applied positive voltage. Since the penetrating sheath develops as positive voltage is increased, the slope of the plot of sheath *vs.* positive voltage is always less than the expected slope, as reported in previous note⁴⁾. This is the reason that at large discharge current the measured sheath radius has only slight dependence on positive voltage.

At high pressure where the drainage is prominent, there is not the same close relation between the drainage and the penetration as at low pressure. The departure of measured sheath radius from theoretical radius is less than that at low pressure. This is due to the fact that at high pressure the penetrating sheath possesses a characteristic more plasma-like than sheath-like.

Next, we are concerned with collection of electron at low pressure where electron collection is determined by orbital motion. Under such condition, an effective collecting radius of probe determines the degree of collection of electron. Using the same procedure as that used in measuring sheath radius under condition that the collection is limited by the sheath area, we can measure the collecting radius.

Fig. 13. Collecting radius and electron current plotted against positive probe voltage under the condition of orbital motion.

Fig. 13 shows typical data obtained for Ar. The measured collecting radius is fairly constant with positive voltage V , independent of plasma density. This would indicate that Langmuir's orbital motion theory of collection⁵⁾ in which collecting radius is roughly proportional to $V^{1/2}$ is not valid, and that Bohm's theory in which collecting radius is independent of V is valid⁶⁾.

In spite of the constancy of collecting radius, a considerable increase in electron collection is obtained with increasing positive voltage, as shown in Fig. 13. This increase is due to the drainage.

(2) Electron collection in magnetic field

Here we deal with the subject of electron collection in magnetic field in order to acquire information on the relation between drainage and voltage-current characteristic.

Since magnetic field used in this measurement is below 1,500 gauss, the ion is hardly affected by magnetic field, while the electron is so affected that the probe characteristic of positive probe is strongly influenced by magnetic field.

Fig. 14. Electron and ion currents as a function of magnetic field applied to the direction of the probe axis.

Such magnetic effect on electron collection can be understood from the fact that the electron current flowing into probe held at the same potential as the plasma potential decreases with increasing magnetic field, while the ion current flowing into probe at an appropriate negative potential with respect to the plasma potential, increases with increasing magnetic field, as shown in Fig. 14. Since there is no doubt that ion collection is not affected by magnetic field, it can be considered as an approximate measure of plasma density.

We may postulate, therefore, that the decrease of electron collection is caused by the magnetic effect. The reason considered for this effect is a decrease of diffusion coefficient⁶⁾.

Next, we consider collection of electron at positive potential. With increasing magnetic field the slope of log-log plot of positive probe characteristics decreases almost independent of

probe orientation. Since from the standpoint of drainage decrease of the slope corresponds to decrease of plasma density, it is concluded that the drainage becomes less pronounced by virtue of decrease of plasma density near probe with increasing magnetic field.

As shown in Fig. 12, the correlation of the plot of electron current *vs.* positive voltage with the plot of the measured sheath radius *vs.* positive voltage in magnetic field is distinct as compared with that in the condition when magnetic field is absent.

A saturation of electron current appearing in high positive voltage range when magnetic field is applied, is the result of a backward flow of electron caused by magnetic field. Also, decrease of sheath radius when magnetic field is applied, can be explained by decrease of effective sheath voltage through circulating motion of electron, while the lowering of plasma density by applying magnetic field should result in large sheath radius.

C. Ion collection affected by disturbance

The probe theory proposed by Langmuir is based upon the assumption that ion sheath is completely screened by the surrounding plasma⁶⁾. In laboratory plasma, however, such screening is not complete.

To study this type of disturbance, it is necessary to obtain knowledge of dependency of the disturbance upon plasma density, probe voltage, dimension of probe and gas pressure.

(1) Voltage-current characteristics

Numerical value of $s = d \log i_p / d \log V$ decreases with rising pressure and with increasing probe radius and plasma density when the rate of expansion of ion sheath accompanied by negative voltage is lowered.

Using a similar procedure for electron, we examine the way in which measured value of *s* differs from the theoretical value.

Experimental results are tabulated in Table II. At all except intermediate pressures, the measured value of *s* is less than the theoretical value based upon the theory that collection is limited by sheath area: as discharge current is lowered, the difference between these values becomes greater.

To see whether or not the value of *s* is affected by the asymmetrical disturbance above mentioned, the measurements are carried out in various tubes, that is, in the ordinary long tube (Fig. 2), the concentric cylinder tube

(Fig. 11) and a large spherical tube with diameter of 15 cm. These results are all consistent in their general dependence upon various parameters.

As a possible cause responsible for discrepancy between measured and theoretical values of s , we may consider that real sheath voltage is less than the applied negative voltage and that the discrepancy between them increases with increasing negative potential. By measuring the real sheath radius by applying a variable-length probe method already proposed by us, an answer may be given.

(2) Penetration of ion sheath

We have already described in a previous paper that in all cases of sheath area limited condition, the sheath radius measured by using the variable-length probe method agreed with or was less than the sheath radius evaluated by using an appropriate space charge equation, and that the discrepancy between them increased with decreasing discharge current or plasma density.

A most acceptable reason for such discrepancy

is that the sheath voltage V is less than the applied negative voltage deduced from probe characteristic.

The expected value V' of the sheath voltage corresponding to the measured radius is always less than the applied voltage and the discrepancy between them becomes large as the applied voltage increases and as the discharge current is reduced.

Now we consider how the disturbance affects the collection of ion on probe. The two important effects are the penetration effect and the scattering effect. The penetration effect results in the sheath voltage being less than the applied voltage, as we described above. Also, it may arise that the penetration effect leads to a decrease of plasma density at the outer boundary of ion sheath.

This is checked by examining how ion current density j at the boundary, estimated from the measured sheath radius and ion current, is changed by increase of negative voltage. Table. III gives some results of this examination, showing that the value of j

Symbols a , b and c in the first column represent the ordinary long cylindrical, concentric cylinder and large spherical tube, respectively. In computation of s in cases when a and b tubes are used, the end effect is taken into account (probe length is 3.3 mm), while in tube c , the end effect is not taken into account, because this effect is eliminated by using variable-length probe method. Symbols L , μ and b in the last column indicate Langmuir's, μ 's and b 's law, respectively.

decreases slightly with increasing negative voltage, except when the pressure is intermediate. This fact serves to explain the reason why the decrease of density by penetration effect can be neglected by us when we determine plasma density of undisturbed plasma.

A proof for such picture is also given by following the way which shows how the slope s obtained by employing the sheath voltage V' instead of the applied voltage agrees with

the theoretical slope.

Results obtained at low pressure are plotted in Fig. 15 (a). In this case the slope s is 0.63 independent of the radius of probe, which is consistent with the theoretical value of Schultz and Brown⁷⁾ based on their assumption that the sheath area limited collection and Langmuir's

(a)

(b)

Fig. 15. Radius of ion sheath plotted against the corrected sheath voltage.
(a) At 2.6×10 mm Hg of Ar, (b) At 0.15 mm Hg of Ar.

law of space charge equation are valid. At high pressure, as shown in Fig. 15 (b), the slope s agrees with the theoretical value obtained by assuming the sheath area limited collection and μ 's law of space charge equation to be applicable. Those results show that the ion current density outside ion sheath is constant. This fact may be interpreted from the point of view of Boyd's sheath criterion⁹.

Finally, we deal with the anomaly observed in intermediate pressure in which the measured slope of log-log plot of ion current *vs.* negative voltage exceeds the theoretically expected slope. This would indicate that in such a pressure the depletion due to elastic scattering affects ion collection, because the extent of a range in which spatial distribution of plasma density changes appreciably because of elastic scattering, becomes comparable to sheath radius.

The fact that at intermediate pressure, value of j estimated by measured sheath radius increases with increasing negative voltage, as seen in results of pressure of 0.35 mm Hg for Ne in Table. III, is successfully explained by such scattering effect.

Fig. 16. A parent-daughter probe.

Furthermore, to prove the existence of a discrepancy between the sheath voltage and applied voltage, we prepare a parent-daughter probe as shown in Fig. 16. As the potential of the parent probe is lowered, the potential of the daughter probe is lowered, but they are not always equal and the difference becomes large especially at high pressure. After the relation between those potentials is checked, we obtain a characteristic of the daughter probe as shown in Fig. 17, in which the electron current at each space potential of the daughter probe is plotted against the negative voltage of the daughter probe. The broken lines in Fig. 17 represent the expected characteristics estimated from the electron temperature by the ordinary technique, that is to say, from the slope of the semi-log plot

of the probe characteristic of the daughter probe when the parent probe is held at the plasma potential.

From this figure, it is found that the electron current at high negative voltage greatly exceeds the expected value. Therefore, it is reasonable to suppose that the sheath voltage is always less than the applied voltage. A comparison of the magnitude of discrepancy observed in the variable-length method with that in this experiment, shows that both are identical numerically.

Fig. 17. Plot of electron current flowing into the daughter probe *vs.* its negative potential with respect to plasma potential. Broken line represents an expected curve which is derived from the measured electron temperature.

Now we may interpret the discrepancy as being the result of a penetration of ion sheath. As in electron collection, the penetrating effect is a result of electrostatic repulsion of accumulated charge. The penetrating sheath thus formed is an intermediate region between plasma and sheath, so that a high voltage drop can be applied across it. This takes place in front of an extracting electrode of discharge type ion source and results in a broadened energy spectrum of ion beam.

§ 4. Conclusions

(1) Inherent disturbance. When a probe is immersed in a plasma, a transition region appears, extending for a considerable distance around the probe, independent of the potential of the probe.

Transition region possesses less density and

has lower potential when compared with density and potential of the undisturbed plasma. The transition region is characterized by a loss of charged particles toward the probe acting as an obstacle.

Especially in d.c discharge plasma, there is an asymmetrical effect which is caused by drift of electron toward anode. As a result, the transition region possesses an asymmetrical configuration along the drift direction, that is to say, behavior of anode side of the transition region is altered by development of a local dense plasma as compensating for the loss of electron near the probe.

Besides the formation of transition, there is another important effect. It is the scattering effect which leads to depletion of charged particle density near probe, and depends upon the mean free path as well as on the geometrical dimension of the probe. At high pressure, this scattering effect plays a surprisingly important role and results in a remarkable error in estimation of plasma density unless it is taken into account.

The transition region is observed over a fairly large area, while the elastic scattering effect is restricted closely around the probe. Consequently we can not observe the scattering effect by means of a thin probe placed close to a large probe, because the thin probe itself possesses an ion sheath of finite thickness.

(2) Disturbance at negative potential. In Langmuir's probe theory it is assumed that the applied probe voltage is impressed across the ion sheath and do not penetrate into the surrounding plasma. However, we observe that at low density plasma, a penetration of probe voltage takes place and becomes prominent with increasing negative probe voltage. Owing to the penetration, a penetrating sheath is formed outside the ion sheath, and as a

consequence, the applied voltage is not only imposed across the ion sheath, but across the penetrating sheath.

This conclusion is confirmed by our probe method using variable-length structure and other examinations using unique probe technique.

(3) Disturbance at positive potential. In positive probe, change of plasma density near probe called "drainage effect" is an important process. This is experimentally verified by the fact that the slope of log-log plot of electron current *vs.* positive probe voltage is startlingly different from the theoretical value.

Also the fact that measured sheath radius is always less than the theoretically expected one, can be identified with the formation of a penetrating sheath just outside the electron sheath, in a way similar to that in the negative probe.

Thus we reveal that collection of electron is determined by the drainage and that ion sheath is influenced by the penetration effect.

Magneto-hydrodynamic Oscillations of a Perfectly Conducting Fluid Sphere Placed in a Uniform Magnetic Field

By Tsuneji RIKITAKE

Earthquake Research Institute, Tokyo University

(Received July 1, 1958)

An attempt to improve theories of magneto-hydrodynamic oscillations of a conducting fluid sphere in a uniform magnetic field is made. Unlike the previous theories which have been developed by M. Schwarzschild and T. Rikitake, analytical expressions for zonal oscillations are obtained rigorously in this paper. It turns out that no eigen-periods are determined accurately. However, they are approximately obtained with drastic simplifications. Two fundamental normal modes of oscillation are also approximately obtained and illustrated.

§ 1. Introduction

Magneto-hydrodynamic oscillations in stars, the sun and the earth's core have been investigated by M. Schwarzschild¹⁾, V. C. A. Ferraro²⁾, T. Rikitake³⁾ and others. All through the studies, it has turned out that magneto-hydrodynamic oscillations of a fluid sphere placed in a uniform magnetic field are quite different from electromagnetic, hydrodynamic or elastic oscillations which have been hitherto examined. In those oscillations, normal modes are usually given as spherical harmonics. However, normal modes for magneto-hydrodynamic oscillations are given as certain combinations of various spherical harmonics.

Schwarzschild¹⁾ has succeeded in obtaining normal modes approximately, though his solutions did not completely satisfy the boundary conditions at the surface of the sphere. Meanwhile, Rikitake³⁾ tried to examine the couplings between poloidal and toroidal magnetic fields of different types. Although he could obtain a set of simultaneous differential equations, which govern the oscillations, in a general form, no accurate solutions of the equations have been obtained, because the equations contained harmonic constituents of successive degree and consequently it was apparently required to solve a set of simultaneous differential equations of infinite numbers with infinite unknowns.

From the theoretical stand-point, however, it is highly desirable to obtain exact normal modes of magneto-hydrodynamic oscillations as well as their eigen-periods as has been done in theories of electromagnetic, hydrodynamic

and elastic oscillations related to a spherical body. The purpose of this paper is to obtain normal modes for a perfectly conducting sphere in an analytical form, though it seems impossible to determine exact eigen-periods.

§ 2. Fundamental Equations

Since we assume that there are no fluid motion and no electric current in the equilibrium state, the fundamental equations can be written as

$$\vec{e} + \vec{v} \wedge \vec{H}_0 = 0, \quad (2-1)$$

$$\text{curl } \vec{e} = -\partial \vec{h} / \partial t, \quad (2-2)$$

$$\text{curl } \vec{h} = 4\pi \vec{i}, \quad (2-3)$$

$$\rho \partial \vec{v} / \partial t = \vec{i} \wedge \vec{H}_0 - \text{grad } p, \quad (2-4)$$

where $\vec{i}$, $\vec{e}$, $\vec{h}$, $\vec{H}_0$, ρ , p and $\vec{v}$ denote respectively electric current density, electric field, magnetic field, steady magnetic field applied from outside, density, pressure and velocity. It is also assumed (1) that the magnetic permeability is unity, (2) that there is no non-electromagnetic force that depends on time, and (3) that the inertia term of fluid motion can be ignored. The fluid is also assumed to be incompressible, so that

$$\text{div } \vec{v} = 0. \quad (2-5)$$

Following Schwarzschild, let us introduce a vector potential $\vec{A}$ which is defined by

$$\vec{v} = \text{curl } \vec{A}. \quad (2-6)$$

In that case, by taking the curl of both sides of (2-4) and applying the formulas of vector analysis, we obtain

$$-\rho D \nabla^2 \vec{A} = H \partial \vec{i} / \partial z, \quad (2-7)$$

$$K^2 = 4\pi\rho D^2 H^{-2}. \quad (2-11)$$

where $\theta=0$ axis is taken as the z -axis. The external magnetic field is parallel to the z -axis, its intensity being denoted by H . D stands for the operator $\partial/\partial t$.

By taking curl of (2-1) and eliminating $\vec{e}$ with the aid of (2-2), we obtain

$$D \vec{h} = H \partial (\text{curl } \vec{A}) / \partial z, \quad (2-8)$$

from which it follows, by taking the curl of (2-8), that

$$4\pi D \vec{i} = -H \partial (\nabla^2 \vec{A}) / \partial z. \quad (2-9)$$

On eliminating $\vec{i}$ from (2-7) and (2-9), we obtain

$$K^2 \nabla^2 \vec{A} = \partial^2 (\nabla^2 \vec{A}) / \partial z^2, \quad (2-10)$$

where

$$K^2 (\nabla^2 A_\phi - A_\phi / (r^2 \sin^2 \theta)) = (\cos \theta \partial / \partial r - \sin \theta \partial / (r \partial \theta))^2 (\nabla^2 A_\phi - A_\phi / (r^2 \sin^2 \theta)). \quad (3-1)$$

It is suggested that the solutions will be of the form such as $\sum_n R_n(r) P_n^1(\cos \theta)$ where P_n^1 is the associated Legendre function of degree n and order 1. If we put

$$A_\phi = \sum_n R_n(r) P_n^1(\cos \theta), \quad (3-2)$$

the lefthand-side of (3-1) is easily reduced to $K^2 \sum_n S_n(r) P_n^1$, where

$$S_n(r) = r^{-2} \frac{d}{dr} \left(r^2 \frac{dR_n}{dr} \right) - n(n+1) r^{-2} R_n. \quad (3-3)$$

Meanwhile, the righthand-side of (3-1) can be rewritten by recurrence formulas as follows;

Righthand-side of (3-1)

$$\begin{aligned} &= (\cos \theta \partial / \partial r - \sin \theta \partial / (r \partial \theta)) \sum_n \left[\frac{dS_n}{dr} P_n^1 \cos \theta - \frac{S_n}{r} \frac{dP_n^1}{d\theta} \sin \theta \right] \\ &= (\cos \theta \partial / \partial r - \sin \theta \partial / (r \partial \theta)) \sum_n \left[\frac{n}{2n+1} \left\{ \frac{dS_n}{dr} - n \frac{S_n}{r} \right\} P_{n+1}^1 + \frac{n+1}{2n+1} \left\{ \frac{dS_n}{dr} + (n+1) \frac{S_n}{r} \right\} P_{n-1}^1 \right] \\ &= (\cos \theta \partial / \partial r - \sin \theta \partial / (r \partial \theta)) \sum_n T_n(r) P_n^1, \end{aligned}$$

where

$$T_n(r) = \frac{n-1}{2n-1} \left\{ \frac{dS_{n-1}}{dr} - (n-1) \frac{S_{n-1}}{r} \right\} + \frac{n+2}{2n+3} \left\{ \frac{dS_{n+1}}{dr} + (n+2) \frac{S_{n+1}}{r} \right\}, \quad (3-4)$$

and repeating the similar reduction, we obtain

$$\text{Righthand-side of (3-1)} = \sum_n U_n(r) P_n^1,$$

where

$$U_n(r) = \frac{n-1}{2n-1} \left\{ \frac{dT_{n-1}}{dr} - (n-1) \frac{T_{n-1}}{r} \right\} + \frac{n+2}{2n+3} \left\{ \frac{dT_{n+1}}{dr} + (n+2) \frac{T_{n+1}}{r} \right\}. \quad (3-5)$$

§ 3. Solutions for Zonal Magnetic Fields

(2-10) has been already obtained by Schwarzschild. He considered solutions only for meridional motions. He described the solutions in terms of power series of radial distance and the periods of free oscillations were estimated from the boundary conditions. In this solutions, however, the boundary conditions were fulfilled only at a few points on the surface of the sphere.

It is intended here to solve (2-10) in a more rigorous way. As has been done by Schwarzschild, it is also assumed that the fluid motion occurs entirely in meridional planes. In that case, the r and θ components of $\vec{A}$ do not exist, so that (2-10) can be written for the ϕ component as

On comparing both sides of (3-1) thus reduced, we see that S_n should satisfy the differential equation

$$K^2 S_n(r) = U_n(r), \quad (3-6)$$

where S_n and U_n are defined respectively by (3-3) and (3-5).

A solution of (3-6), which does not become infinite at $r=0$, is to be of the form

$$S_n(r) = (2n+1)(Kr)^{-1/2} I_{n+(1/2)}(Kr), \quad (3-7)$$

where $I_{n+(1/2)}$ is the modified Bessel function of degree $n+\frac{1}{2}$. When we consider recurrence formulas for modified Bessel functions, it is easily shown that

$$\begin{aligned} \frac{dS_{n+1}}{dr} - (n-1) \frac{S_{n+1}}{r} &= K(2n-1)(Kr)^{-1/2} I_{n+(1/2)}(Kr), \\ \frac{dS_{n+1}}{dr} + (n+2) \frac{S_{n+1}}{r} &= K(2n+3)(Kr)^{-1/2} I_{n+(1/2)}(Kr), \end{aligned}$$

so that (3-4) gives

$$T_n = K S_n,$$

and consequently we have

$$U_n = K T_n = K^2 S_n$$

from (3-5). We thus see that S_n as given in (3-7) is the solution of (3-6).

Introducing such a function to S_n of (3-3), the differential equation for R_n is obtained as

$$r^{-2} \frac{d}{dr} \left(r^2 \frac{dR_n}{dr} \right) - n(n+1) r^{-2} R_n = C(2n+1)(Kr)^{-1/2} I_{n+(1/2)}(Kr), \quad (3-8)$$

where C denotes a free constant which determines the amplitude of oscillation. It is easily seen that the particular solution of (3-8) is given by $K^{-2} C(2n+1)(Kr)^{-1/2} I_{n+(1/2)}(Kr)$, so that the general solution, which does not become infinite at $r=0$, can be written as

$$R_n(r) = \lambda_n r^n + K^{-2} C(2n+1)(Kr)^{-1/2} I_{n+(1/2)}(Kr), \quad (3-9)$$

in which λ_n is a constant which will be determined later. In the above process, it is obvious that $\sum_n$ should be read $\sum_{n=1}^{\infty}$.

Since A_ϕ is given by (3-2) together with (3-9), the typical term of r , θ and ϕ components of $\vec{v}$ is calculated as

$$\vec{v} = \sum_{n=1}^{\infty} \begin{pmatrix} \frac{R_n}{r} \frac{1}{\sin \theta} \frac{d}{d\theta} (\sin \theta P_n^1) \\ -\frac{d(rR_n)}{rdr} P_n^1 \\ 0 \end{pmatrix} = \sum_{n=1}^{\infty} \begin{pmatrix} \frac{n(n+1)}{r} \frac{R_n}{r} P_n \\ \frac{d(rR_n)}{rdr} \frac{dP_n}{d\theta} \\ 0 \end{pmatrix} \quad (3-10)$$

with the aid of (2-6). From (2-8), the corresponding magnetic field inside the sphere is obtained as

$$\vec{h} = D^{-1} H \sum_{n=1}^{\infty} \begin{pmatrix} \frac{n(n+1)}{r} \frac{V_n(r)}{r} P_n \\ \frac{d(rV_n)}{rdr} \frac{dP_n}{d\theta} \\ 0 \end{pmatrix}, \quad (3-11)$$

where

$$V_n(r)=\frac{n-1}{2n-1}\left\{\frac{dR_{n+1}}{dr}-(n-1)\frac{R_{n-1}}{r}\right\}+\frac{n+2}{2n+3}\left\{\frac{dR_{n+1}}{dr}+(n+2)\frac{R_{n+1}}{r}\right\}, \tag{3-12}$$

which can be also transformed to

$$V_n(r)=(n+2)\lambda_{n+1}r^n+K^{-1}C(2n+1)(Kr)^{-1/2}I_{n+(1/2)}(Kr). \tag{3-13}$$

§ 4. Boundary Conditions for Fluid Motion

1) *Rigid boundary*

If the sphere is surrounded by a rigid surface, the normal component of velocity should vanish at $r=a$, whence, from (3-9) and (3-10), we have

$$\lambda_n=-a^{-n}(2n+1)K^{-2}C(Ka)^{-1/2}I_{n+(1/2)}(Ka). \tag{4-1}$$

Putting (4-1) into (3-13), we obtain

$$V_n(r)=CK^{-1}[(2n+1)(Kr)^{-1/2}I_{n+(1/2)}(Kr)-(n+2)(2n+3)(Ka)^{-3/2}I_{n+(3/2)}(Ka)(r/a)^n]. \tag{4-2}$$

2) *Free boundary*

In this case, the condition which should be satisfied at the boundary is

$$p=0. \tag{4-3}$$

We can calculate $\text{grad } p$ and subsequently p from (2-4). After some calculations, p is found to be

$$p=-K^2\sum_n[(n+1)\lambda_nr^n+2K^{-2}C(2n+1)(Kr)^{-1/2}I_{n+(1/2)}(Kr)]P_n, \tag{4-4}$$

hence (4-3) implies

$$\lambda_n=-2K^{-2}C\frac{2n+1}{n+1}a^{-n}(Ka)^{-1/2}I_{n+(1/2)}(Ka). \tag{4-5}$$

Putting (4-5) into (3-13), we obtain

$$V_n(r)=CK^{-1}[(2n+1)(Kr)^{-1/2}I_{n+(1/2)}(Kr)-2(2n+3)(Ka)^{-3/2}I_{n+(3/2)}(Ka)(r/a)^n]. \tag{4-6}$$

No detailed discussion about cases of free boundary, however, will be made in this paper because we are mainly interested in oscillations of a sphere surrounded by a rigid boundary such as the earth's core.

§ 5. Eigen-values

The eigen-values of K should be determined by the boundary conditions that electric and magnetic fields are continuous at $r=a$. However, unlike usual hydrodynamic, elastic or electromagnetic oscillations of a sphere, no rigorous eigen-equation is likely to be obtained because the components of magnetic field inside the sphere are given by infinite series such as that shown in (3-11). In the following, a method for obtaining approximate eigen-values will be described.

In the case of a rigid boundary, from (3-11) and (4-2), the magnetic field at $r=a$ should be written as

$$\vec{h}_{r=a}=\begin{cases} D^{-1}H C f(\theta;Ka) \\ D^{-1}H C g(\theta;Ka) \\ 0 \end{cases}, \tag{5-1}$$

way. Some crude approximations of eigen-values will be obtained in the following with drastic simplifications.

From what we have been dealing with in Section 3, we see that there are no couplings between harmonic constituents of even and odd modes separately. This fact has been also pointed out in the writer's previous paper³⁾.

1) Odd mode

If we disregard terms for $s > 1$ and $n > 1$ in (5-9), (5-9) is reduced to

$$(Ka)^2 I_{1/2}(Ka) = 15 I_{3/2}(Ka), \quad (5-10)$$

which may be regarded as the crude approximation of the eigen-equation for the lowest odd mode. In that case, the eigen-values become

$$Ka = 0.76i, 5.77i, \dots, \quad (5-11)$$

hence the largest period of this oscillation mode is given by

$$T = 5.2\pi^{3/2}\rho^{1/2}aH^{-1}. \quad (5-12)$$

2) Even mode

In this case, we take into account only the term for $s=2$ and $n=2$, ignoring higher degree terms. We therefore have, from (5-9),

$$(Ka)^2 I_{3/2}(Ka) = 28 I_{7/2}(Ka), \quad (5-13)$$

which gives

$$Ka = 2.08i, 7.49i, \dots, \quad (5-14)$$

and the largest period becomes

$$T = 1.9\pi^{3/2}\rho^{1/2}aH^{-1}. \quad (5-15)$$

§ 6. Oscillation Modes

Since $\text{div } \vec{v} = 0$ and $\text{div } \vec{h} = 0$, we may express $\vec{v}$ and $\vec{h}$ in terms of appropriate Stokes' "stream functions", ψ and u respectively. The curves for $\psi = \text{constant}$ will then be the stream-lines of the motion, while the curves for $u = \text{constant}$ give the equations of the lines of force of the magnetic field. As has been shown by Ferraro²⁾, there are relations such as

$$\vec{v} = \begin{pmatrix} -\frac{1}{r^2 \sin \theta} \frac{\partial \psi}{\partial \theta} \\ \frac{1}{r \sin \theta} \frac{\partial \psi}{\partial r} \\ 0 \end{pmatrix}, \quad (6-1)$$

$$\vec{h} = \begin{pmatrix} -\frac{1}{r^2 \sin \theta} \frac{\partial u}{\partial \theta} \\ \frac{1}{r \sin \theta} \frac{\partial u}{\partial r} \\ 0 \end{pmatrix}. \quad (6-2)$$

From (3-10), (3-11) and (5-3), we see that the stream functions become

$$\psi = -r \sum_n R_n \sin \theta P_n^1, \quad (6-3)$$

$$u = -D^{-1} H r \sum_n V_n \sin \theta P_n^1 \quad \text{for } r < a, \quad (6-4)$$

$$u = -\sum_s \frac{h_s}{s} r^{-s} \sin \theta P_s^1 \quad \text{for } r > a. \quad (6-5)$$

Corresponding to the even mode discussed in the last section, we obtain

$$u = -D^{-1} H r V_2(r) \sin \theta P_2^1 \quad \text{for } r < a, \quad (6-6)$$

$$u = -\frac{h_2}{2} r^{-2} \sin \theta P_2^1 \quad \text{for } r > a, \quad (6-7)$$

where only the terms for $n=2$ and $s=2$ are taken into account as before. h_2 is determined

Fig. 1. Magnetic lines of force for the lowest even mode. External magnetic field is directed upwards.

Fig. 2. Stream-lines of motion for the lowest even mode. External magnetic field is directed upwards.

by (5-4) or by the continuity of u at $r=a$, we therefore have

$$h_2 = 2D^{-1}Ha^3V_2(a). \quad (6-8)$$

The magnetic lines of force can be calculated from (6-6) and (6-7) as shown in Fig. 1.

It is obvious from (3-12) that the stream function of the motion is described, to the degree of the present approximation, as

$$\phi = -rR_1 \sin \theta P_1^1 \quad (6-9)$$

from which the stream-lines are calculated as shown in Fig. 2. All through the calculations in the above, the lowest eigen-value given

in (5-14) is to be taken. In that case, it is easily seen that higher degree terms for u and ϕ become fairly small, so that the above procedure, in which only the spherical harmonic of lowest degree is taken, would be justified.

As for the odd mode, we obtain

$$u = -D^{-1}HrV_1(r) \sin \theta P_1^1 \quad \text{for } r < a, \quad (6-10)$$

$$u = -h_1 r^{-1} \sin \theta P_1^1 \quad \text{for } r > a, \quad (6-11)$$

where

$$h_1 = D^{-1}Ha^2V_1(a), \quad (6-12)$$

and

$$\phi = -rR_2 \sin \theta P_2^1. \quad (6-13)$$

With these expressions, the magnetic lines of force and stream-lines of motion for this mode are obtained as shown in Figs. 3 and 4 respectively, while the lowest eigen-value given in (5-11) are adopted.

§ 7. Discussion and Concluding Remark

It is interesting that the analytical expression of normal oscillation modes are given by (3-10) and (3-11). However, it is not possible to determine accurate eigen-periods of free oscillations. A crude estimate with some simplification suggests that the eigen-periods for oscillations of the lowest mode are nearly the same as those obtained in the previous paper. If we imagine a perfectly conducting liquid sphere, of which the density and the radius are assumed to be 10 g/cm^3 and 10 cm respectively, placed in a magnetic field of 10 gauss, the period for the lowest odd mode is estimated as 110 sec., while that for the lowest even mode as 33 sec. However, it is not possible to make such an experiment because of low conductivity of existing fluid.

If we consider problems of astronomical and geophysical scale, the present study has some bearing. But since the results in this paper are more or less similar to those obtained in references mentioned in the introduction, no detailed discussion in this line will be tried here.

Chemical and Thermal Polish of KCl Crystals

By Masayoshi SAKAMOTO and
Shunsuke KOBAYASHI

*Physics Department, Tokyo College of Science
Shinjuku-ku, Tokyo, Japan*

(Received July 31, 1958)

KCl crystals are so soft that its surfaces are likely to have many dislocations by any slight mechanical shocks from outside¹⁾. In other words, they are apt to be contaminated in the meaning of dislocation theory. In order to remove these contaminations effectively, we have some methods of chemical and thermal polish²⁾.

Fig. 1. An example of a chemically polished surface.

Fig. 1 is an example of a deep chemical polish with H_2O only. In the field of Fig. 1(a) there are one oblique cleavage step and two glide bands running in the $[100]$ direction, which have existed since before the generation of other stripes of dislocation groups. Besides these we can see about four stripes of dislocation groups in the $[010]$ direction, which have a large density of dislocation respectively. These stripes resulted from the rubbing of KCl crystal surface with a sheet of paper by about 3 cm in distance under the loading of 20 gr/cm² in weight. A picture after the chemical polish of about 5 seconds in time and about 100 μ in depth with H_2O is Fig. 1(b) and it is well recognized that the stripes of dislocation groups in high density and also the

oblique step vanished completely.

Adequate heat treatment can give us an effect of polish which never cause so much volumal change as chemical polish. Fig. 2(b) shows the stripes of dislocation groups generated on a cleaved surface by rubbing under the same load as in Fig. 1. In this picture two glide bands and one boundary can be seen clearly the same as the picture before the rubbing [Fig. 2(a)]. After the heat treatment of 600°C in temperature, one hour in duration and 40°C/hour in its cooling rate, we got a result of Fig. 2(c). Contrary to the facts that the charac-

Fig. 2. An example of a thermally polished surface

teristic stripes of dislocation groups and glide hands vanished undoubtedly, it is notable that the boundary and most of cleavage steps did not vanish through treatment.

Contamination in the meaning of dislocation theory and also geometrical roughness in usual meaning on KCl crystal surfaces will be removed by using together both methods of chemical and thermal polish described above. Both are usable

for the removing of surface contaminations, but especially chemical polish is effective for the removing of cleavage steps and thermal polish for the removing of glide bands.

Nuclear Magnetic Resonance Experiments of I^{127} in KI

By Junkichi ITOH and Yukio YAMAGATA

*Department of Physics, Faculty of Science,
Osaka University*

(Received July 7, 1958)

We have made a series of experimental studies on nuclear magnetic resonance of alkali halides. In this note, the temperature dependence of the spin-lattice relaxation time and chemical shift of iodine nuclear magnetic resonance in KI crystal will be reported.

Fig. 1 shows the results of T_1 measurements, in which $\sqrt{1/T_1}$ is plotted against temperature, T . Now, time dependent nuclear electric quadrupole

Fig. 1.

interaction caused by lattice vibration probably contributes mainly to the spin-lattice relaxation in alkali halides. Kranendonk¹⁾ calculated T_1 theoretically by assuming the electric quadrupole interaction arises from electrostatic field gradient due to relative displacement of ions by lattice vibration, while later Yosida and Moriya²⁾ extended the theory to the case in which a small degree of covalency exists in the bond between positive and negative ions. According to these both theories, $\sqrt{1/T_1}$ is

nearly proportional to T , in the temperature range of our measurements (line A in Fig. 1). The experimental plots deviate from this straight line at higher temperatures. As for this deviation, higher order terms in T in the theoretical calculation and effects due to the temperature variation of Debye temperature and sound velocity in the crystal are negligibly small, and the implicit temperature dependence due to thermal expansion of the lattice seems to be most important. Using known value of the thermal expansion coefficient and assuming a relation $\lambda(\text{covalency}) \propto \exp(-R/0.345)$ (R is the interionic distance in Å), which Yosida and Moriya assumed in their calculation, a numerical calculation was done (curve B in Fig. 1). The result of the calculation explains the experimental data in some extent, but, to interpret the experiments perfectly, much stronger dependence of λ upon R should be assumed, which seems to be inadequate. Kranendonk's theory gives much less improvement than Yosida and Moriya's one does.

The experimental results of the temperature dependence of the chemical shift are shown in Fig. 2. Here relative shifts of the resonance frequency from that at room temperature are plotted against T . A numerical calculation of the temperature dependence of the shift was made along the line of Yosida and Moriya's theory (curve A in Fig. 2).

Fig. 2.

In this calculation, it is needed to use the absolute shift of solid resonance from pure iodine ion resonance. Solid KI shows a chemical shift of -1.7×10^{-4} relative to dilute KI aq., while by the measurement of concentration dependence of the shift of KI aq., a shift of the order of -6×10^{-4} was found for the resonance in dilute KI aq. from that of free iodine ion³⁾. Therefore, we took the sum of these two shifts (-7.7×10^{-4}) as the true chemical shift of solid KI from pure iodine ion at room temperature. Though general feature of the theoretical temperature dependence agrees with the experiments, there appears an abnormal behavior of the measured shifts at higher temperatures. These discrepancies at higher temperatures are still opened to question

both for T_1 and the shift.

The absolute values of T_1 and the shifts can be interpreted by Yosida and Moriya's theory, at least in their orders of magnitude, if a covalent degree of about 5 percent is assumed in each bond between K^+ and I^- , though this value of covalency seems to be too large. Kranendonk's theory, with appropriate value of Sternheimer antishielding coefficient gives also right order of magnitude for T_1 , but Sternheimer's ion core deformation may not give a shift of the order of magnitude mentioned above.

A Proposed Explanation of Irradiation Growth of Uranium

By Ryukiti R. HASIGUTI, Hideo SAKAIRI*
and Tetuya SUGAI

*Department of Metallurgy, University
of Tokyo*

(Received July 8, 1958)

The problem of irradiation growth of uranium is far from being fully understood at present. It is observed that an α uranium crystal elongates in $[010]$ direction, and contracts in $[100]$ direction under the neutron irradiation. No dimensional change is observed in $[001]$ direction. To explain this phenomenon, two concurrent theories, i.e. anisotropic diffusion theory¹⁾ and slip and twin theory²⁾, were proposed and are still being examined by many investigators. We have taken another step forward along the line of twin theory, and then combined it with the precipitation scheme of interstitials and vacancies produced by irradiation. This proposed theory will be discussed here briefly.

Pugh²⁾ proposes a theory, in which he states that local elongations in $[010]$ direction and local contractions in $[100]$ direction are effected by successive twinings caused by stresses of thermal spikes. However his statement is only qualitative in nature, and he does not designate any specific twinning system.

We propose $(130) [\bar{3}10]$ twinning caused by thermal stresses due to local heating by thermal spikes. This kind of twinning is most frequent in α uranium, and is actually observed in large quantity in thermal cycled uranium. As is shown in Fig. 1, average deformation of various $\{130\} \langle \bar{3}10 \rangle$ type

twins results precisely in $[010]$ elongation and $[100]$ contraction.

Fig. 1.

Fig. 2.

The most important requirement for the mechanism of uni-directional elongation is the irreversibility of deformation. The slip mechanism is *a priori* reversible. But the twinning is considered to be irreversible according to the circumstances, although the conditions for a twin not to make detwinning are not yet known.

The internal stress produced by small local twinning, mentioned above, must be released in some ways in order that the growth process is continued without an appreciable hardening. We consider that the stress release is achieved by means of precipitation of vacancies and interstitials which were produced by irradiation.

Precipitation of vacancies means here the absorption of vacancies by $[100]$ edge dislocations, which climb in $[010]$ direction, resulting in a contraction in $[100]$ direction. Interstitials tend to precipitate in (010) plane, because the atomic bond is considered to have covalent nature in (010) plane, and metallic nature between these planes. The precipitation of interstitials in (010) plane results in an elongation in $[010]$ direction.

Fig. 2 shows a schematic representation of the proposed mechanism of precipitation. Tw is a small twinned region, where there exist $[010]$ elongation and $[100]$ contraction in average. The internal stress will be released, if the surrounding medium deforms in the same way as in Tw. Thus the precipitation of interstitials (I) in (010) planes and the climbing of dislocations (d) will bring about the deformations indicated by the arrows in the figure.

We did not hitherto mention about slips at all. But we think that slips do actually take place. They may probably release the internal stresses partly.

Seigle and Opinsky¹⁾ discussed the anisotropic diffusion of interstitials and vacancies. This may also help the growth phenomenon to occur in addition to the mechanism described here.

The irradiation growth does not occur both at

* Graduate Course in Physics

low temperatures (say at liquid air temperature) and at high temperatures (for example at 500°C). This is explained by the facts that diffusion and precipitation become very slow at low temperatures, and that twinning becomes very difficult to take place at high temperatures.

On the Conduction Mechanism of Oxide Coated Cathode

By Hiroyuki MIZUNO

Matsushita Electronics Corporation, Takatsuki

(Received July 15, 1958)

According to Loosjes-Vink¹⁾ the conduction of matrix of oxide coated cathode was explained by dual mechanisms. One mechanism is the electron conduction through the oxide coating particle which is seen in the so called low temperature region. The other mechanism is the conduction through the electron cloud emitted from the grains which is seen in the high temperature region. The experimental tube used in their work consists of two symmetrical cathodes which pressed against each other by springs. The essential feature of the experimental tube is the dimensional symmetry about the center of (BaSr)O matrix.

We have measured the potential distribution in oxide coated cathode for low and high temperatures by means of potentiometer flowing the current to one direction. The design of tested cathode is si-

Fig. 1. Test tube for potential measurement.

milar to Loosjes-Vink's which is shown in Fig. 1. The obtained results are given in Fig. 2 which were contradicted to Loosjes-Vink's theory. From those results one can see that nearly all applied voltage falls across the contact layer of so called reverse direction between (BaSr)O and metal sleeve in low temperature region where-as that is monotonous in high temperature region*. When the current direction is changed, the same phenomenon appeared in the opposite contact layer.

It seems reasonable to conclude that the barrier layer across the contact between matrix and sleeve has main role in the usual measurement of conductivity of oxide coated cathode in low temperature region. It is pointed out by Mott-Schottky³⁾ that there is the rectification property at contact boundary between metal and semiconductor. Accordingly, it is supposed that there should be the rectification in the contact layer between (BaSr)O and metal sleeve. Therefore the conduction of oxide coated cathode should be explained in view point of rectification theory. Wright⁴⁾ had tried for the first time to explain the conduction in high temperature region by assuming that the electrons have to pass through the barrier layer between (BaSr)O and sleeve. However his explanation is also contra-

Fig. 2. Resistance of the contact layer in either reverse or forward direction with various applied voltages.

* Note: Metson²⁾ carried out the potential measurement only in high temperature region with outaware of low temperature.

dicted to our results.

According to our opinion one has to do essentially with newly proposed mechanism as shown below:

In low temperature region, the conduction current is mainly determined by the resistance of barrier layer of reverse direction produced between (BaSr)O and sleeve which is represented by the rectification formula proposed by Mott-Schottky whereas in high temperature region, as almost all electrons emitted from grains have sufficient energy to pass through the barrier thermally the conduction depends almost upon the properties of electron gas present in the pores.

Details of our consideration on our explanation and some experiments which are carried out for further confirmation of that will be published later.

The Far Infrared Absorption of Sulfides, Selenides and Tellurides of Zinc and Cadmium

By Akiyoshi MITSUISHI, Hiroshi YOSHINAGA and Shigeru FUJITA

Department of Applied Physics, Faculty of Engineering, Osaka University, Osaka, Japan

(Received July 31, 1958)

The far infrared absorption due to the lattice vibration of ZnS, ZnSe, ZnTe, CdS, CdSe and CdTe was measured. These materials have the simple crystal structure such as zincblende or wurtzite and no measurement of the far infrared absorption has been reported previously except ZnS.

The absorption spectra were recorded by the far infrared spectrograph which was constructed in this laboratory and reported by Yoshinaga et al¹⁾.

As the single crystals of these materials which were thin enough to produce the appropriate transmission and at the same time large enough to cover the relatively large slit of the spectrograph could not be obtained and only a small amount of the materials was supplied except ZnS and CdS, recourse was made to the polyethylene suspension technique which was proposed by Yoshinaga and Oetjen²⁾. A small amount of the finely powdered

material was mixed with small pieces of polyethylene by the heated roll to produce the uniform suspension of the material in polyethylene film. The thickness of a polyethylene film was about 0.3 mm and the concentration ranged from 1 to 2.5 mg/cm². The evaporated layers of ZnS and CdS on polyethylene films were also measured.

For each material investigated only one strong absorption band was observed. The wave number of the absorption band is given in Tab. I together with the crystal structure. As is clear from Tab. I, the material with smaller reduced mass has the

Table I.

Material	Structure*	Freq. (cm ⁻¹)
ZnS	Z	310
ZnS	W	300
ZnSe	Z	215
ZnTe	Z	190
CdS	Z	270
CdS	W	260
CdSe	W	185
CdTe	Z	150

* Z: zincblende, W: wurtzite.

larger wave number as in the case of alkali halides³⁾.

The zincblende type lattice has one molecule in its unit cell and in the harmonic approximation only one optically active mode is expected. This agrees with the present experimental result.

For the wurtzite type lattice which contains two molecules in the unit cell two optically active modes are expected and two bands or the indication of the splitting of the band was reported for BeO and ZnO⁴⁾. In our case hexagonal ZnS and CdS gave only one strong absorption band which shifted to a little smaller wave number than the cubic one and showed no indication of the splitting nor the broadening compared with the cubic one. Also this was true for the hexagonal CdSe.

In the case of the evaporated layer, the absorption band was observed at 275 cm⁻¹ for ZnS and 245 cm⁻¹ for CdS. The same result has been reported for ZnS⁵⁾. The slight differences of these values from those of the powdered materials would be due to the effect suggested by Fröhlich and Mott⁶⁾.

Kröger and Meyer⁷⁾ deduced the infrared lattice frequency of CdS to be 227 cm⁻¹ from the spacing of the line series in the edge emission. The present investigation gives the experimental value of 245 cm⁻¹. The difference is somewhat large compared with the case of ZnS which showed the good agreement⁷⁾.

The authors wish to thank Mr. H. Suzuki of

Kyushu University for providing ZnSe, ZnTe, CdSe and CdTe and Mr. S. Ibuki of Mitsubishi Electric Manf. Co. for ZnS and CdS.

The Far Infrared Absorption of Ferrites

By Akiyoshi MITSUISHI, Hiroshi YOSHINAGA
and Shigeru FUJITA

Department of Applied Physics, Faculty
of Engineering, Osaka University,
Osaka, Japan

(Received July 24, 1958)

Recently Waldron¹⁾, using the KBr pellet technique, has measured the infrared absorption of several ferrites in the spectral region from 4000 to

280 cm^{-1} . In this spectral region he found two strong absorption bands due to the lattice vibration of ferrite.

Assuming the ions in the primitive unit cell to be subdivided into two MO_4 groups (M stands for a divalent ion) and one Fe_4 group with tetrahedral symmetry, he obtained theoretically four optically active modes of lattice vibrations. The frequencies of these vibrations were labeled ν_1 , ν_2 , ν_3 and ν_4 in the order of decreasing wave number. Among these, ν_3 and ν_4 have low values and absorption bands due to these vibrations are to be observed beyond 280 cm^{-1} , the lowest limit of the spectral region of his spectrograph.

It is the purpose of this note to report the experimental results on ferrites obtained with our far infrared spectrograph.

The ferrites investigated were ZnFe_2O_4 , NiFe_2O_4 , CoFe_2O_4 and MgFe_2O_4 in powdered form. A suitable amount of the powder was suspended uniformly in polyethylene film by a heated roll.

The far infrared spectrograph was constructed in our laboratory and has been reported by Yoshinaga et al²⁾. The spectral region covered in this investigation was from 500 to about 10 cm^{-1} .

Fig. 1 shows the transmission curves obtained. The absorption band at about 400 cm^{-1} for all the ferrites examined is the same as ν_2 band obtained by Waldron. Another fairly strong band which is only observed for ZnFe_2O_4 at 330 cm^{-1} has also been reported by him. The slight difference in the wave number of these bands is due to the different matrix used. Furthermore, a weak shoulder band was observed at 425 cm^{-1} for ZnFe_2O_4 in our investigation. These bands were obtained with the

Fig. 1. Far infrared absorption and reflection spectra of ferrites. (Fluctuations of points in the lower wavenumber region are due to the interference effect of the polyethylene film.)

concentration of about 1 mg/cm^2 .

Increasing the concentration to about 7 mg/cm^2 another band which might correspond to ν_3 band was observed except MgFe_2O_4 . The absorption band of ZnFe_2O_4 was very sharp and located at 169 cm^{-1} . The absorption bands of NiFe_2O_4 and CoFe_2O_4 were rather broad as in the case of ν_2 band and observed at 196 cm^{-1} and 181 cm^{-1} respectively. We could not find any definite absorption band of MgFe_2O_4 in the corresponding spectral region.

The observation was extended up to about 1 mm region and the concentration increased to 25 mg/cm^2 to find the ν_4 band, but no absorption band could be obtained for all the ferrites examined.

The reflectivity of the sintered plates of ZnFe_2O_4 and MgFe_2O_4 is also measured and given in Fig. 1. The reflectivity maxima which correspond to ν_2 band of both materials and to 330 cm^{-1} band of ZnFe_2O_4 are clearly shown.

The authors wish to thank Mr. B. Kubota of Matsushita Electric Industrial Co. for providing the ferrites examined.

Growth and Extinction of Guanidine Aluminum Sulfate Hexahydrate Crystals

By Atsuo NISHIOKA and Kyoze SEIKAWA

*Electrical Communication Laboratory,
Musashino, Tokyo, Japan*

(Received December 17, 1957)

Forroelectricity of Guanidine aluminum sulfate hexahydrate (GASH) has been found by Holden et al¹⁾, but detailed studies are yet to be done. We have observed the growth of single crystals under crossed nicols and have observed several curious facts. Fig. 1 shows one of the crystals which seemed to be so called *c*-plate, but most of them did not show any extinction around *c* axis (Fig. 2). Viewing from *a*-axis, straight extinction was observed in *a* or *c* direction (Fig. 3 and 4). From X-ray analysis of these crystals, *c*-axis is found to be perpendicular to hexagonal plane.

Next, we observed the growing process of seed crystals from saturated solution under polarizing microscope at room temperature (Fig. 5 and 6 under parallel nicols). At the stage in Fig. 6, the nicols

$\times 100$

were crossed and the viewing field was rotated. As shown in Fig. 7, 8 and 9, the crystal A is always dark around the *c*-axis, showing that this is a *c*-plate crystal. But the crystal B has extinction in a special direction, and so appears to be a kind of *a*-plate. The crystal C seems to be mixed in *a* and *c*-plate. These anomalous behaviors of B and C crystals, which is not expected from the results

of X-ray analysis of the crystals shown in Fig. 3 and 4, would probably be related with crystal habits of GASH. Further study is now going on.

The Reaction $F^{19}(d, n)Ne^{20}$ and the Energy Levels of Ne^{20}

By Susumu MORITA and Kenji TAKESHITA

*Department of Physics, Faculty of Science,
Kyushu University, Fukuoka, Japan*

(Received, July 7, 1958)

The energy spectra of neutrons emitted in the reaction $F^{19}(d, n)Ne^{20}$, produced by the 2.17 MeV deuteron, were measured with nuclear plates disposed at angles of 0° to 165 degrees, with respect to the incident deuteron, at intervals of 15 degrees. The general features of the spectra were consistent with the evaporation model. From these spectra, the energy levels of Ne^{20} were found at excitation energies of 1.74 ± 0.03 , 4.20 ± 0.04 , 4.96 ± 0.05 , 5.62 ± 0.04 , 6.80 ± 0.01 , 7.16 ± 0.09 , 7.41 ± 0.05 , 7.90 ± 0.04 , 9.15 ± 0.04 and 10.01 ± 0.03 MeV. Some evidences for the existence of new levels at 0.65 ± 0.04 , 2.53 ± 0.07 , 8.32 ± 0.03 , 8.71 ± 0.01 and 9.50 ± 0.04 MeV were also obtained. The Q -value for the ground state transition was determined to be 10.81 ± 0.03 MeV. The angular distributions of the neutrons leading to the ground state and the lowest four excited states, with exception of the uncertain states, were obtained and compared with the stripping theory. The agreement is not very good. The relative values of total cross sections for each neutron group were estimated.

§ 1. Introduction

It has been proved that the shell model is successful for the interpretation of properties of low-lying levels of light nuclei and the configuration mixing is very probable in the states of nuclei of mass number near 20. On the other hand, the energy levels of C^{12} and O^{16} have been well fitted with the predictions of alpha particle model. From these point of view, it seems interesting to investigate the level structure of $4n$ -self conjugate nucleus Ne^{20} . The characteristics of the 4.97 MeV level in Ne^{20} is of special interest for thermonuclear reaction in stars.

The energy level scheme of Ne^{20} has been studied mainly by the reaction $Na^{23}(d, \alpha)Ne^{20(1,2)}$ and the elastic and inelastic scattering of protons by $Ne^{20(3,4)}$, and the consistent results have been obtained. However, the spins and parities have been determined only for the ground state and the 1.63 MeV state.

As for the reaction $F^{19}(d, n)Ne^{20}$, Bonner, in 1940⁵⁾, measured the energy spectrum of neutrons, produced with deuteron beam of 0.9 MeV, at an angle of 90 degrees with respect to the incident deuteron by means of cloud chamber. Powell, in 1943⁶⁾, measured the same spectrum at an angle of 100 degrees with nuclear plate. In 1955, Calvert et al.⁷⁾ measured the angular distributions of neu-

trons, produced with the 9.06 MeV deuterons, in the angular range of 0 to 60 degrees by means of fast neutron spectrometer and obtained the results consistent with the stripping theory. But in their work, the three levels in the range of 4 to 6 MeV of excitation energy, which had been well established by the study of the reactions emitting charged particles, were not observed.

The aim of the present experiment is to measure the energy spectra of neutrons, at the deuteron energy of 2.17 MeV, at various angles in the whole angular range and to determine the energy levels of Ne^{20} , with the reaction $F^{19}(d, n)Ne^{20}$ as accurately as possible. Moreover, we intended to obtain the angular distributions of neutrons, which will be useful for the interpretation of the mechanism of the (d, n) reaction at rather lower energy of deuteron.

§ 2. Experimental Arrangements and Procedures

The experimental arrangement is shown in Fig. 1. The deuterons were accelerated to 2.22 MeV by the Van de Graaff generator at Kyushu University, whose voltage was calibrated with the resonances in the reaction $F^{19}(p, \alpha)O^{16}(\gamma)O^{16}$ and the accuracy of deuteron energy was about 0.5 percent. The thickness

of the target of CaF_2 , which were evaporated onto a silver plate, was determined to be 100 KeV for proton of 1.3 MeV by measuring the apparent width of the resonance peak of the reaction $\text{F}^{19}(p, \alpha)$. The target could be rotated with a small magnet and removed from the deuteron beam in the background runs. The beam duct in front of the target chamber, shown in Fig. 1, was made of thin brass tube

Fig. 1. Arrangements of the target and photographic plates.

of wall thickness of 0.5 mm to minimize the absorption and scattering of neutrons emitted backwards. The attenuation of neutron intensity in the materials which were present between the target and plates was estimated by considering their total neutron cross section. The correction was found to reach maximum at the direction of 75 degrees and amounted to 14 percent. The inner surface of beam duct hit by the deuteron beam were all covered with silver plates to avoid the neutron production.

The bombardment was carried out with beam current of 1 to 2 microamperes for about nine hours. The neutrons were detected with Fuji ET-2E emulsion of 250 microns thickness and these plates were arranged in the angular range of 0 to 165 degrees in laboratory system, with respect to the direction of the incident deuteron beam, at intervals of 15 degrees. The glancing angle of neutron to the emulsion surface was chosen to be 10

degrees and the distance between the target and the centers of scanned area of each plate was 19 cm. Those tracks of recoil protons were recorded which had horizontal angles to the direction of incident neutrons of less than or equal to 10 degrees and dip angles of less than or equal to 10 degrees in the unprocessed emulsion⁸⁾. The energy spectra of neutrons were obtained by applying the corrections due to the different probabilities with which recoil protons with different energies escape from the emulsion surface and due to the variation of $n-p$ scattering cross section with neutron energy.

As the range-energy relation of the Fuji ET-2E emulsion for protons had not been known yet, it was obtained by measuring the recoil-proton ranges in the emulsion exposed to the neutrons of known energies from the reactions $\text{D}^2(d, n)\text{He}^3$ and $\text{T}^3(d, n)\text{He}^4$. The result is shown in Fig. 2. In this figure, the

Fig. 2. Range-energy relation of the emulsion Fuji ET-2E for protons. Curve A is the calculated one and curve B was determined by experiment.

curve A is the calculated one from the stopping powers of the chemical components of the dried emulsion and the curve B is determined by the experiments. The abscissa shows the energies of protons E_p , which were determined from the known energy of neutron E_n by the relation $E_p = 0.961 E_n$ ⁸⁾. The three points on curve B at lower proton energies were determined based on the neutrons emitted in the directions of 0, 45 and 120 degrees in the reaction $\text{D}^2(d, n)\text{He}^3$, produced by deuterons of 2.04 MeV and the point of the higher energy was determined by the neutron

emitted in the direction of 90 degrees in the reaction $T^3(d, n)He^4$, produced by deuterons of 170 KeV.*) The energy spectra of these standard neutrons are shown in Fig. 3. The two

Fig. 3. Energy spectra of neutrons emitted from the reactions $D^2(d, n)He^3$ and $T^3(d, n)He^4$.

points on the curve B of Fig. 2 in the middle energy range of protons correspond to the neutrons emitted in the directions of 0 and 75 degrees in the reaction $F^{19}(d, n)Ne^{20}$ leading to the first excited state at 1.63 MeV of Ne^{20} . As is shown in Fig. 2, this range-energy relation gives an energy value three percent larger than that given by the calculated curve A.

§ 3. Results and Discussions

The examples of energy spectra of neutrons from the reaction $F^{19}(d, n)Ne^{20}$, thus obtained, are shown in Fig. 4. The energy spectra of neutrons greater than 2 MeV were investigated on the three plates placed at 15, 90 and 165 degrees, and one of these, obtained at 165 degrees, is shown in Fig. 4 (a). From these spectra, in the range of excitation energy higher than 6 MeV, the states of Ne^{20} were found at 8.32 ± 0.03 , 8.71 ± 0.01 , and 9.50 ± 0.04 MeV, besides the 6.80 ± 0.01 , 7.16 ± 0.09 , 7.41 ± 0.05 , 7.90 ± 0.04 , 9.15 ± 0.04 , and 10.01 ± 0.03 MeV states, which were obtained previously in the reactions $Ne^{20}(p, p')Ne^{20}$ (4)

*) This bombardment was carried out in the nuclear laboratory of Kōnan University. The authors wish to express their cordial thanks to the staff of that laboratory for their kind assistance.

Fig. 4 (a). Energy spectrum of neutrons from the reaction $F^{19}(d, n)Ne^{20}$. The histogram shows the spectrum of neutrons of energy higher than 2 MeV, obtained at the direction of 165 degrees. The smooth curves show the calculated spectra based on the evaporation model. The curves A, B and C correspond to the nuclear temperature $\Theta = 2.06, 2.33$, and 2.72 MeV, respectively.

Fig. 4 (b) and (c). Energy spectra of neutrons from the reaction $F^{19}(d, n)Ne^{20}$. The curves show the detailed features of neutrons of energy higher than 6 MeV, obtained at the directions of 0 and 75 degrees.

and $\text{Ne}^{20}(\alpha, \alpha')\text{Ne}^{20\ 9)}$. The 7.16 MeV state will be the unresolved overlapping of the 7.18 and 7.22 MeV states found in the reaction $\text{Ne}^{20}(\alpha, \alpha')\text{Ne}^{20}$. The smooth curves in Fig. 4 (a) were calculated by the following equation¹⁰⁾, based on the statistical theory of compound nucleus formation.

$$I(\varepsilon)d\varepsilon = \text{const } \varepsilon \sigma_c(\varepsilon) \omega_{\text{Ne}}(E_a + Q - \varepsilon) d\varepsilon$$

in which $Q=10.81$ MeV is the energy release of this reaction, E_a the energy of incident deuteron in the center of mass system, ε the energy of emitted neutron, $\sigma_c(\varepsilon)$ the cross section for the formation of a compound nucleus by an incident neutron of energy ε and ω_{Ne} the level density of the residual nucleus Ne^{20} as a function of excitation energy. The values of $\sigma_c(\varepsilon)$ were referred to the table given by Blatt and Weisskopf and the level density used are based on Fermi gas model and is given by

$$\omega(E) = C \exp(2\sqrt{aE})$$

in which E is the excitation energy and a and C are constants. The calculations were carried out for $a=1.73, 2.36$, and 3.00 MeV⁻¹, and best fit was obtained for $a=2.36$ MeV⁻¹, which corresponds to the nuclear temperature $\Theta=2.33$ MeV.

Fig. 5. The level schemes of Ne^{20} , determined from the energy spectra of neutrons. The abscissa shows the angles at which the nuclear plates were disposed. The dotted lines show the mean values of the energy states. The range of excitation energy higher than 6 MeV were studied only on the plates placed at 15, 90 and 165 degrees.

It will be seen in this figure that the theoretical curve is in fair but not good agreement with the experimental result, and it will be probable that the compound nucleus formation is predominant in this reaction, although some contribution from the stripping reaction may not be excluded. This result is consistent with the angular distributions of neutrons, which will be described later.

The energy spectra of neutrons of energy higher than about 5 MeV, where the spectra can be decomposed into discrete groups of neutrons, were studied in more details on all the twelve plates. The smoothed curves in Fig. 4 (b) and (c) show the spectra, thus obtained on the plates disposed at angles of 0, and 75 degrees. The energy levels of Ne^{20} determined from these spectra are shown in Fig. 5 and the mean values of the excitation energies of these states are shown in Table I, together with the results previously obtained by other investigators. The Q -value for the ground state transition was estimated to be 10.81 ± 0.03 MeV, which is to be compared with the values of 10.645 MeV given by Ajzenberg and Lauritzen¹¹⁾ and 10.80 ± 0.2 MeV given by Segre¹²⁾. The three levels at 4.20, 4.96, and 5.62 MeV, which were completely missing in the results obtained by Calvert et al.⁷⁾, were distinctly observed and in good agreement with the results obtained by the reactions emitting charged particles. The second and the fourth peaks in Fig. 4, shown with arrows, might correspond to the level of Ne^{20} at 0.65 and 2.53 MeV. As these peaks are so small that the existence of levels corresponding to them is not certain. But these two small peaks were observed in almost all of the energy spectra and the variation of the position of these peaks with the angles of observation were consistent with the reaction $\text{F}^{19}(d, n)\text{Ne}^{20}$. Moreover, the possible contaminants responsible for these higher energy neutron groups are B^{11} , Na^{23} , and Al^{27} , and the result of the chemical analysis^{*)} of the sample of CaF_2 used for the target indicated that the abundances of these impurities were less than 0.01 percent.

For the estimation of the intensities of

*) This chemical analysis was performed by Prof. Yoshimura and Mr. Takashima of Dept. of Chemistry of Kyushu University. The authors wish to express cordial thanks to them.

neutron groups overlapping each other, the upper and lower limits of the energy of each group were estimated as follows. The highest end was obtained by merely extrapolating the slope of the higher energy side of each spectral peak, and the lowest end was assumed to be lower by eight percent than the neutron energy of the peak. These assumptions were made because the shapes of the well separated peaks are consistent with them, as shown in Figs. 3 and 4. The uncertainties caused by such decomposing procedures are included in the following angular distributions as well as the statistical one. The theoretical curves, shown in the following figures, were calculated by the Born approximation theory¹³⁾ of stripping for $l_p=0$ and 2, using a nuclear radius $r=(2.7+1.22A^{1/3})\times 10^{-13}$ cm for F^{19} . As the ground state of F^{19} has spin 1/2 and even parity and is supposed to be $(1d_{5/2})^2 s_{1/2}$ configuration, the angular distri-

butions corresponding to the excited levels of Ne^{20} in the same shell as the ground state, that is $(d_{5/2})(s_{1/2})(d_{3/2})$, would fit the theoretical curves of $l_p=0$ or 2.

The ground State

The angular distribution of neutron leading to the ground state, including the neutrons leading to the 0.65 MeV state, is shown in Fig. 6 (a). The ground state of Ne^{20} , which is even-even nucleus, has spin 0 and even parity and has been supposed to have the configuration $(1d_{5/2})^2(2s_{1/2})^2$. The angular distribution in the forward direction obtained by Calvert et al.⁷⁾, was in good agreement with the theoretical curve of $l_p=0$. As is shown in Fig. 5 (a), the present result is not consistent with the theoretical curve of $l_p=0$ and is rather near to that of $l_p=2$. This disagreement may be due to the effect of Coulomb barrier, which was not taken into account in

Fig. 6. The angular distributions of neutrons from the reaction $F^{19}(d, n)Ne^{20}$, leading to the various states of Ne^{20} . The smooth curves were computed with the stripping theory for $l_p=0$ and 2, using a nuclear radius $R=6 \times 10^{-13}$ cm.

the theoretical calculation, or may be due to the configuration mixing and the interference with the compound nucleus formation. The effect of configuration mixing will be excluded because of the fact that the Calvert's result was obtained with a considerably higher energy of deuteron and it is not likely that the higher angular momentum transfer becomes more probable in lower bombarding energy.

1.74 MeV State

This level coincides well with the 1.63 MeV state, obtained by the reactions emitting charged particle, within the accuracy of the determination of the neutron energy. It has been proved that this level has spin 2 and even parity by the measurement of angular correlation in the reaction $Na^{23}(p, \alpha)Ne^{20}$ ¹⁴⁾. The angular distribution in the forward direction, obtained by Calvert et al.⁷⁾, well fitted the theoretical stripping curve of $l_p=2$. The present angular distribution, shown in Fig. 5 (b), is not much consistent with the theoretical curve.

2.53 MeV State

In the early experiments on the beta decay of F^{20} , the 2.2 MeV state has been reported^{15), 16)} and some indication for the existence of this

state was found in the reaction $F^{19}(d, n)Ne^{20}$ also by Powell⁹. But this state has been missing in the charged particle measurements. Jelley, in 1950²⁷, found the 2.45 MeV state in the measurements of beta- and gamma-rays from F^{20} . This value is consistent with the present result. The existence of this state is probable but not certain yet.

4.20, 4.96 and 5.62 MeV States

The angular distributions of neutrons leading to the 4.20, 4.96 and 5.62 MeV states are shown in Fig. 6 (c), (d) and (e), respectively. The angular distributions in Fig. 6 (c) and (e) are rather isotropic compared with the others. As is usual in the second excited state of even-even nucleus, the 4.20 MeV state may have spin 4 and even parity. The reason why these levels were missing in the Calvert's experiment and appeared distinctly in the present experiment is not clear but it seems to be probable that the stripping process is predominant in this reaction at higher energy of deuteron and in our case, the compound nucleus formation becomes predominant.

The 4.96 MeV state is just above the sum of the masses of O^{16} and He^4 , which is 4.476 MeV higher than the ground state of Ne^{20} and the characteristics of this state has much effect on the abundance of neon in stars. It will be seen in Fig. 5 (d) that the transition to the 4.96 MeV state may be interpreted by the stripping reaction of $l_p=0$. Accordingly, this state might have spin 0, or 1, and even parity.

The relative values of total cross sections

Table II. Relative values of total cross sections for each neutron groups.

Excitation energy of Ne^{20} corresponding to each neutron groups	Relative values of total cross sections. (Present experiment)	Relative values of cross sections at peaks. (Calvert's results)
0	0.43	0.16
1.74	0.89	1.00
2.53	0.37	0
4.20	0.54	0
4.96	0.52	0
5.62	1.0	0

corresponding to each neutron group are shown in Table II. These values are normalised to the largest one for the 5.62 MeV state transition. The values, obtained by Calvert et al.⁷, for the relative values of cross sections at their peaks, are shown in the third column.

The authors wish to express their cordial thanks to Prof. I. Nonaka and all other staff of the nuclear laboratory of Kyushu University for their support and discussion throughout this work. Thanks are also due to Mr. Y. Kozeki of Research Laboratory of Fuji Photographic Film Industry for his kind preparation of nuclear plates and to Miss Y. Kajiwara, Miss M. Hirakura and Miss R. Hanada for their skilful scanning of the nuclear plates. This work has been supported by the Scientific Expenditure of the Ministry of Education.

Differential Elastic Scattering of 14 MeV Neutrons in Aluminum, Iron, Lead and Bismuth for Large Angles

By Kazunori YUASA

*Department of Physics, Faculty of Science,
Konan University, Kobe*

(Received July 5, 1958)

The absolute differential cross sections for the elastic scattering of 14 MeV neutrons in Al, Fe, Pb and Bi have been measured for large angles up to 170° . The neutrons generated by $^3\text{T}(d, n)^4\text{He}$ reactions were scattered by the disk-shaped scatterer, and counted by the $n-\alpha$ coincidence circuit with the resolving time of 4 ns. An anticoincidence method was used to reduce the accidental coincidences between the α -particles and the neutrons which run directly to the detector from the target.

Except for the lighter nucleus, the angular distributions obtained fit fairly well with distributions based on the optical model theory employing a surface imaginary part and a real spin-orbit coupling term.

§ 1. Introduction

Experimental data on the differential cross sections for elastic scattering of neutrons have been reported by many authors¹⁾ for the energy region 1~5 MeV, and have been compared with the optical model theory developed by Feshbach, Portor and Weisskopf²⁾. Recently some experimenters³⁻¹¹⁾ have extended the energy region up to 14 MeV. The use of high energy neutrons has the following advantage. By the optical model theory, the elastic cross section is divided into the "compound elastic" cross section and "shape elastic" cross section. The shape elastic scattering occurs without the formation of a compound nucleus, while the compound elastic scattering comes from the formation of a compound nucleus and the subsequent emission of the incident particle through the entrance channel. Since the observed differential elastic cross section is an unknown mixture of these two cross sections, it cannot be compared directly with the calculated cross section. The compound elastic scattering, however, is appreciable only at the neutron energy below several MeV. If the neutrons of higher energy were used, the possibility of compound elastic scattering would become very small, more nuclear levels being available for inelastic scattering. In consequence, the theory can be tested more rigidly by comparing directly with the calculated results. The theoretical angular distribution depends upon the detailed assumptions made

about the potential used in the calculations especially at large angles. The data for 14 MeV neutrons published so far have, however, been confined to the relatively small angular range. Therefore, the experiments at larger angles are desirable but are very difficult owing to the extremely small cross section.

Quite recently, a combination of the ring geometry and the time-of-flight technique by a pulsed neutron source has been adopted by Wong, Anderson, Gardner and Nakada^{12,13)}. This technique seems very promising for the measurements of large angle scattering, but there are two limitations in the ring geometry: (1) There is difficulty for many elements in constructing large ring-shaped scatterers for their high prices. (2) The energy spread becomes considerably large except when the ring-shaped sample is placed symmetrically with respect to the direction of the deuteron beam.

The present experimental method is of course quite suitable for measuring expensive elements, but the author tentatively performed the measurements on such commoner elements as aluminum, iron, lead and bismuth, because the theoretical calculations for these nuclei were available in detail for the whole angular range¹⁴⁾.

§ 2. Experimental Method

The 14 MeV neutrons were generated by the $^3\text{T}(d, n)^4\text{He}$ reaction. A target of T-Zr or

T-Ti was bombarded with a magnetically analyzed beam of 150 keV deuterons from a Cockcroft-Walton accelerator¹⁵.

The deuteron beam was deflected by 60° in a double focusing electromagnet and focused on a target about 65 cm apart from the magnet. The beam was defined by a slit of elliptical shape to give a round spot of diameter 5 mm on a target which was inclined by 45° to the beam. The current density of the beam was made to be less than $10 \mu\text{A}/\text{cm}^2$ to avoid the local heating of the target plate.

Precautions were taken to diminish the scattering and absorption of neutrons by the target chamber. The chamber was made of an iron cylinder of 2 mm thickness with two acrylic windows for alpha-particle counters and a window of copper foil of 0.15 mm thickness through which the neutron beam passed out to the scatterer. The T-Zr or T-Ti target was 1 cm in diameter and was fixed on a copper slab 2 mm thick and it was maintained at a fixed temperature by circulating hot water. The back of the target was holed to avoid the absorption and scattering of neutrons.

The number of neutrons emitted was monitored by a plastic scintillator at a fixed position and a counting-rate meter connected to the alpha-particle detector. The neutron intensity was kept as constant as possible during the measurements.

ing the measurements.

Fig. 1 shows the experimental arrangements. The scattering experiments were performed at 90° in the direction of the deuteron beam. The alpha-particles from the reaction ${}^3\text{T}(d, n){}^4\text{He}$ were detected in the counter A, and only the neutrons emitted in coincidence with those alpha-particles were recorded.

The background coincidence rate, taken without scatterer, consisted mainly of accidental coincidences between the alpha-particles and the neutrons which wet directly from the source to the neutron counter. To avoid these accidental coincidences, the alpha-particles corresponding to those neutrons were detected by another alpha-counter B, the pulses of which were used to cancel the pulse of the corresponding neutrons.

In this way, the accidental rate was reduced without using an absorber between the source and the neutron counter so that the counter was allowed to come nearer to the target without causing much increase of background rate, and thus the scattering measurements at large angle were made possible.

Disk-shaped scatterers of diameter of 10 cm, 15 cm and 20 cm respectively were used, the thicknesses of which were such that 10 to 15 per cent of the incident neutrons were scattered elastically. The larger and thicker scatterers among these were used only for measurements at larger angles.

The scatterer was placed roughly tangent to the locus of point for which the scattering angle was constant, and the angular resolution could be limited in a range from $\pm 2^\circ$ to $\pm 4^\circ$ in spite of the comparatively large diameter of the scatterer.

Fig. 1. Experimental arrangements.

- n : neutrons scattered by S,
- n_D : neutrons which go directly to the detector from the target,
- α_A, α_B : alpha-particles corresponding to n and n_D respectively,
- A: alpha-particle detector (for coincidence),
- B: alpha-particle detector (for anticoincidence),
- D: neutron detector,
- S: scatterer,
- T: target. (The deuteron beam injects perpendicularly to the figure at T.)

Fig. 2. Position of neutron detector.

The differential elastic cross section was deduced from the results of the following three runs (Fig. 2). (1) The scatter was removed, the neutron detector was placed at A and the coincidence rate N_0 between neutron and alpha-counter was measured. (2) The detector was transferred to the point B, the scatterer was placed at S and the coincidence rate N_S was measured. (3) The scatterer was removed, the detector was placed at B, and the background N_B was counted. N_0 , N_S and N_B were all normalized for a given number of monitor counts.

The absolute differential cross section can be calculated from the scattering ratio defined as:

$$g(\theta_0) = \frac{N_S - N_B}{N_0}, \quad (2.1)$$

where θ_0 is the scattering angle at the center of the scatterer. It is not necessary to determine the value of the absolute neutron flux in this case.

To make the coincidence efficiency the same for the three measurements (1), (2) and (3) it was necessary that

$$r_0 \simeq r_1 + r_2. \quad (2.2)$$

Since the neutrons were measured in coincidence with the alpha-particles of the reaction, the background counting rate at the N_0 measurement was negligibly small.

The angle θ_0 may be varied either by changing the distance between the source and the neutron detector, or by changing that between the source and the scatterer, or by changing both distances. For some value of θ_0 , several different geometries were used to confirm the results. $g(\theta_0)$ was measured over the angular range from 70° to 170° for aluminum, iron and bismuth, and from 90° to 170° for lead.

§ 3. Detectors

A cylindrical stilben of 3/4" in diameter and 3/4" in length was used as the neutron detector. The crystal was connected optically through an acrylite light guide to an RCA 6810 photomultiplier. The discriminator bias was set to count only the pulses corresponding to recoil protons of energies greater than 10~11 MeV. Such a criterion can eliminate almost all inelastically scattered neutrons, for a great majority of these neutrons have con-

siderably lower energies¹⁶). The gamma rays were also rejected by this bias setting and further by means of the flight time. The pulse height spectrum of the neutron detector for 14 MeV neutrons and gamma-rays from radium is shown in Fig. 3.

The alpha-particle detectors were both the sheet of plastic scintillator of 5 cm in diameter and 0.12 mm in thickness, which was prepared by pressing a small disk-shaped plastic scintillator* with two glass plates in an oven heated at 160°C ¹⁷.

The pulse height distribution for alpha-particles from polonium is shown in Fig. 4. This curve was taken by coupling the scintil-

Fig. 3. Differential pulse height distribution of neutron counter. The curve for the gamma-ray was taken only to show its maximum pulse height, and there was no definite relation between the intensity of the gamma-ray and the neutron.

Fig. 4. Pulse height distribution of plastic scintillator for alpha-particles from polonium.

lator sheet directly to the face of a photomultiplier EMI 5311 with some silicone oil. During the scattering experiments, however, each sheet was attached to the inner surface of the respective acrylic window of the target chamber. The scintillator was covered by 0.39 mg/cm^2 aluminum foil to stop the scattered deuteron and the light from the deuteron beam. To each outer surface of the acrylic window, the head of RCA 6810 photomultiplier was optically connected.

All the three photomultipliers were operated at 2000~2300 volts with their anodes at the grounded potential. The dynode voltage dividing ratio was taken as specified by the manufacturer¹⁸⁾. The magnetic shield of 0.9 mm permalloy sheet* was provided to each photomultiplier. This sheet was also used as an electrostatic shield by being maintained at the same potential as that of the photocathode. The electrostatic shield was necessary to suppress the noise due to internal discharge of the surface charge in the tube. The high potential was supplied from a common source developed by K. Sugiyama¹⁹⁾ in this laboratory. It was very stable against the primary voltage change and the drift was less than 0.05 per cent for many hours.

§ 4. Electronic Circuits

The block diagram of the overall electronic circuit is shown in Fig. 5.

Fig. 5. Block diagram of electronic circuits.

The fast rising pulses from the anode of each photomultiplier were directly fed to a coaxial cable RG 63/U** or C44T***. Each cable

* Permalloy P. C., Sumitomo Metal Industries, LTD., Osaka, Japan.

** Fujikura Densen LTD., Tokyo, Japan.

*** Transradio LTD., London SW 7 England.

was grounded at the end near the photomultiplier anode through a resistance equal to the characteristic impedance of the cable. To the other end, the diode coincidence circuit and another coaxial cable of L cm in length were connected. This cable was short-circuited at the farther end and clipped to the width of $2Lt$ seconds, where t means the time delay of the cable per cm. The value of $2Lt$ was chosen usually at about 4 ns (1 nano second = 10^{-9} second) for coincidence pulses, and about 10 ns for anticoincidence pulses.

The coaxial cables were also used to give suitable delays to the pulses from the photomultipliers. Fig. 6 shows the relation between

(a) coincidence (b) accidental coincidence
Fig. 6. Time delay of each pulse.

the time delays for the pulses from each counter. In the figure, n is the pulse due to the neutron elastically scattered and n_D is that due to the neutron which goes directly to the detector from the target. α_A and α_B are the alpha-pulses from the counter A and B respectively (Fig. 1). These pulses are produced at different time instants depending on the flight time of the neutrons or alpha-particles between the target and the detector. In Fig. 6 (a), the neutron pulse n and the pulse α_A are produced by the identical neutron production. These pulses were made to arrive at the same time to the coincidence circuit by suitable delay lines. In Fig. 6(b), the neutron pulse n_D is caused by the identical nuclear reaction as the pulse α_B . The n_D - and α_A -pulses have reached to the coincidence circuit simultaneously only by chance, though they are independent of each other. This chance coincidence is avoided by the anticoincidence of the α_A - and α_B -pulses as described before. The latter pulse is made to arrive at the coincidence circuit about 5 ns earlier and end slightly later than the neutron pulse to make sure of the anticoincidence.

The diode coincidence circuit is shown in

Fig. 7. It is, in principle, the circuit of R. Madey²⁰⁾, though we have made some modifications. The most essential point of the modifications was the attachment of an anti-coincidence circuit, which was specially designed to work satisfactorily when the time rate of the anticoincidence pulses is very large. E180F tube at the input was used as an amplitude limiter. The anticoincidence circuit requires the pulses of the same polarity and height as those of the pulses for coincidence, but the pulse height and the duration were made somewhat larger than those of the pulses for coincidence to provide against possible fluctuations not only in the pulse height but also in the time when pulse arrives

at the coincidence circuit due to uncertainty in the transit time in the photomultiplier.

The pulse lengthener circuit was just the same as that used by Madey. The linear amplifier and discriminator were of the types described by Jordan and Bell²¹⁾.

The positive dynode pulses from the neutron counter and the alpha counter A were used for amplitude discrimination for selection of neutron energy and to avoid spurious count from alpha-counter. These pulses were amplified by the respective amplifier with low gain and discriminated. They were clipped by shorted delay line to 100 ns at the input of the linear amplifier. The linear amplifier was of conventional ring-of-three unit, the rise time of

Fig. 7. Schematic diagram of fast coincidence circuit.

Fig. 8. Schematic diagram of EFP60 trigger discriminator circuit.

which was about 100 ns. Fig. 8 shows the amplitude discriminator of EFP60 trigger type^{22, 23)} which generates output pulses of 100 ns in duration. The trigger level of this circuit was determined by changing the bias voltage of the cathode follower V_{1A} by a 10 turn helicalohm*. The duration of the output pulse was determined by the delay line between the anode and grid of EFP60 tube. In the present circuit, RG65/U of 80 cm length was used. The output pulses from the two EFP60 discriminators were fed to the two grids of 6BN6 tube in a coincidence circuit. The time resolution of this circuit was about 100 ns. The number of alpha-particles was so large that a coincidence circuit with such relatively short resolving time was required.

The output of this 6BN6 tube was coupled to the output of the fast coincidence circuit by a slow coincidence circuit. The resolving time of this circuit was about $2\mu s$, and its output was led to the scaler through a uni-vibrator and a gate tube. The scaler was of scale-of-100 type modified from a Higinbotham circuit²⁴⁾. The spurious counts and natural background counts were not observed for several hours.

§ 5. Calculation of the Cross Section

The relation between the scattering ratio $g(\theta_0)$ defined by (2.1) and the differential cross section $\sigma(\theta)$ is expressed by the following equation:

$$g(\theta_0) = \frac{N_S - N_B}{N_0} = \int_V r_0^2 r_1^{-2} r_2^{-2} S(E) f(\theta) \sigma(\theta) \times \{\exp[-\mu'(d+e)]\} n dV, \quad (5.1)$$

where θ is the scattering angle in the laboratory system, $S(E)$ is the sensitivity of the detector for scattered neutrons, $f(\theta)$ is the correction factor for the variation of the detector sensitivity due to the incident angle of the neutrons, μ is the total absorption coefficient, n is the number of atoms per unit volume in the scatterer and what are represented by the remaining symbols are seen in Fig. 2.

The integration has to be performed over the entire volume V of the scatterer. The factor $S(E)$ is derived from the energy E of the scattered neutron. E is given approximately as follows:

$$E = \frac{A-1+\cos\theta}{A+1-\cos\theta} E_0, \quad (5.2)$$

where E_0 is the energy of the incident neutron and A is the mass number of scattering nucleus.

The factor $f(\theta)$ was determined by a test measurement, but it was almost unity, the angular sensitivity of the detector being nearly constant.

Since r_0^2 and n are constant and $\sigma(\theta)$, $S(E)$ and $f(\theta)$ are nearly constant in the formula (5.1), $g(\theta)$ can be rewritten approximately as follows:

$$g(\theta_0) = \sigma(\theta_0) r_0^2 S(E) f(\theta) n \int_V r_1^{-2} r_2^{-2} \times \{\exp[-\mu(d+e)]\} dV, \quad (5.3)$$

where $\sigma(\theta_0)$ is the differential elastic cross section at the center of the scatterer. This integration was performed numerically by dividing the scatterer into several zones. Thus the curve of differential elastic cross section was obtained to a first approximation. The correction for the angular spread due to the finite dimensions of the scatterer and the detector was carried out by integrating the formula (5.1) using the value of $\sigma(\theta)$ from the above curve. This process was continued until the shape of the curve did not appreciably change any more, but this correction itself was very small in the present angular range where the dip and rise of the curves were not so distinct and the iteration was not necessary adequate in most cases.

Since the thickness of the scattering samples was so chosen that they scatter only about 10 to 15 per cent of the incident neutrons elastically, the correction for the multiple scattering was not so large compared to experimental errors in our data and only the correction for the double scattering was performed. In calculating the correction, it was noticed that the angular distributions were strongly peaked in the forward direction. The details are given in Appendix.

§ 6. Results and Discussions

The experimental results are represented in Figs. 9~12, and the numerical data are shown in Table I. The errors indicated in the curves and table are the statistical ones, and they do not include the other experimental errors which are usually much smaller than

* Sakae Tsushin Kogyo Co. LTD. Tokyo, Japan.

this. Only the error due to the normalization of the neutron intensity amounts to about 6 per cent. The errors of the corrections for multiple scattering and angular resolution were far smaller because the corrections themselves were small.

Fig. 9. Differential elastic cross section of aluminum.

Fig. 10. Differential elastic cross section of iron.

Fig. 11. Differential elastic cross section of lead.

Fig. 12. Differential elastic cross section of bismuth.

In the angular range below 60° , the experimental results³⁻¹¹⁾ closely fitted into the theoretical calculations based on the optical model theory when simple square-well potential was used. At angles larger than 60° , however, it was difficult to fit by such a simple well potential. Culler, Fernbach and Sherman²⁵⁾ used the tailed-well including the spin-orbit potential, but there appeared some pronounced dips which were not observed experimentally. Bjorklund, Fernbach and Sherman²⁶⁾ used a tailed-well as the real part, and a Gaussian type potential for the imaginary part, namely:

$$\left. \begin{aligned} \text{real part:} \quad & U = U_0/[1 + \exp(R - R_0)/a], \\ \text{imaginary part:} \quad & V = V_0 \exp[-(R - R_0)/b^2], \end{aligned} \right\} \quad (6.1)$$

where $U_0 = 40.3$ MeV, $V_0 = 8$ MeV, $R_0 = (1.2A^{1/3} + 0.64)$ Fermi, $a = 0.6$ Fermi, $b = 0.977$ Fermi.

Their results still show too large dips at large angles. Recently they have extended their calculations so as to include the spin-orbit potential as well as the central potential¹⁴⁾. The potential used in their calculation was of the form:

$$V = V_{CR}\rho(r) + iV_{CI}q(r) + V_{SR}\left(\frac{\hbar}{\mu c}\right)^2 \frac{1}{r} \frac{d\rho(r)}{dr} \sigma l,$$

where

$$\left. \begin{aligned} \rho(r) &= 1/[1 + \exp(r - R_0)/a], \\ q(r) &= \exp[-(r - R_0)^2/b^2], \end{aligned} \right\} \quad (6.2)$$

and

$$R_0 = r_0 A^{1/3}.$$

Lab angle	Differential cross section, millibarns per steradian							
	Aluminum		Iron		Lead		Bismuth	
	$\sigma(\theta)$	error	$\sigma(\theta)$	error	$\sigma(\theta)$	error	$\sigma(\theta)$	error
70°	46.2	4.5	12.8	4.3			83.2	9.8
80°	22.6	4.2	17.1	3.2			30.5	5.7
90°	16.0	5.0	24.7	4.5	13.1	4.2	14.7	3.9
100°	14.1	4.0	12.4	4.7	24.9	4.1	23.6	4.1
110°	18.5	3.8	10.3	3.8	14.0	3.8	14.9	4.0
120°	11.7	4.1	6.1	2.8	11.8	3.5	8.0	3.2
130°	11.8	3.8	12.6	3.5	9.9	3.2	12.8	3.0
135°	8.2	3.6	12.2	3.4				
140°	6.1	4.2	10.0	3.6	11.9	3.0	12.5	2.8
150°	7.9	4.0	11.9	4.5	7.7	3.3	7.1	3.1
160°	10.3	4.3	8.3	4.8	13.8	4.7	11.8	4.0
165°	12.0	5.8						
170°	7.8	5.3	7.9	5.3	21.6	6.8	16.7	5.6

(The notation is the same as that used by Riesenfeld and Watson²⁷.) The numerical values in the formula are as follows: $V_{OR}=44$ MeV, $V_{OI}=11$ MeV, $V_{SR}=8.3$ MeV, $a=0.65$ Fermi, $b=0.98$ Fermi and $r_0=1.25$ Fermi. Their results are shown by solid-line curves in the figures.

Our results for medium weight and heavy nuclei are in good agreement with the theoretical curves. They also agree with the data of Coon and Davis³), Gardner *et al.*¹³) and the normalized results by Berko, Whitehead and Groseclose²⁸). Whereas, the data of Mehlhorn⁹) and Rhein⁴) up to the scattering angle of 150° seems to be inconsistent with ours.

In aluminum, our experimental values are appreciably larger than the theoretical ones for the backward scattering. The optical model theory may not be applied satisfactorily for a lighter nucleus such as aluminum.* Fujimoto and Hossain²⁹) and Burge *et al.*³⁰) have shown, however, that the optical model with a simple square-well is able to explain fairly well the experimental data of the angular distribution up to 160° for a nucleus of much smaller mass number such as nitrogen or oxygen. The discrepancy between theory and

experiments still remains unexplained. The experiments for other light nuclei and the reexamination of theory will be necessary.

Appendix

The Correction for the Multiple Scattering

The calculations for multiple scattering have been performed by several authors, but little of them was found to be applicable to the present case. Langsdorf *et al.*¹) derived an exact solution of the multiple scattering by expanding the differential cross section in Legendre's polynomial, but their calculation was very complicated. In the present measurements, very simple assumptions can be used, because the scattering of neutrons is strongly predominant in the forward direction. It is to be noticed, however, that this approximation is only applicable to large angle scat-

* Note added in proof: Recently it was shown by M.P. Nakada *et al.* (Phys. Rev. 110 (1958) 1439) for C and Be and by J. H. Coon *et al.* (Phys. Rev. 111 (1958) 250) for C that the observed differential cross section differ considerably from the results of optical model calculations.

tering in which the rise and dip of the cross section are not appreciable.

Since the thicknesses of the scatterers are so chosen that only 10 to 15 per cent of the incident neutrons are elastically scattered, it is always sufficient to consider only the correction for the double scattering as stated before.

Suppose the sample to be a infinite slab of thickness t . Moreover, we assume, for the sake of simplicity, that the incident and scattered neutrons are collimated and are in the same plane perpendicular to the slab. Then, the flux Φ_1 of the neutrons which are scattered once in the slab, is given as:

$$\begin{aligned}\Phi_1 &= \Phi_0 \cos \theta_1 \int_0^t n \sigma(\phi_0) \\ &\quad \times \exp \{-(\sec \theta_1 + \sec \theta_2) \mu x\} \frac{dx}{\cos \theta_1} \\ &= \Phi_0 \sigma(\phi_0) \frac{n}{b} \{1 - \exp(1 - bt)\}, \quad (\text{A.1})\end{aligned}$$

where

$$b = (\sec \theta_1 + \sec \theta_2) \mu.$$

In this formula, Φ_0 is the flux of the incident neutrons, n is the number of nuclei in the scatterer and $\sigma(\phi_0)$ is the differential cross section of elastic scattering. The meaning of other notations can readily be seen from Fig. 13.

Next, we consider the neutrons which suffer the double scattering in the slab. Since the scattering is strongly peaked in the forward direction, only the two extreme cases shown in Fig. 14 (a) and (b) will occur in practice

when the over-all scattering angle is large. Since the probability for occurrence is nearly equal in the two cases, we can consider only one of the cases (e.g. the case (a)) and mul-

Fig. 13. Diagram of single scattering.

tiply the result by two. The flux $d\Phi_2$ of the neutrons which make the first scattering at a point of depth x and then the second scattering at a point of depth $x+u$, as shown in Fig. 14 (a), is given as:

$$\begin{aligned}d\Phi_2 &= \Phi_0 \sigma(\phi_1) n dx \frac{r dr d\phi}{R^2} \sigma(\phi_2) n \\ &\quad \times \exp[-\{x \sec \theta_1 + R + \sec \theta_2(x+u)\} \mu] du. \quad (\text{A.2})\end{aligned}$$

where R is the distance between the two points. Thus, the total flux Φ_2 of the neutrons which suffer the double scattering in the slab and emerge at the angle θ_2 is expressed in the form:

$$\begin{aligned}\Phi_2 &= 2\Phi_0 n^2 \sigma(\phi_2) \int_0^t dx \int_0^{t-x} du \int_0^{2\pi} d\phi \int_0^\infty \sigma(\phi_1) \frac{r dr}{R^2} \\ &\quad \times \exp[-\{x \sec \theta_1 + R + \sec \theta_2(x+u)\} \mu]. \quad (\text{A.3})\end{aligned}$$

(a)

(b)

Fig. 14. Diagram of double scattering.

Since the scattering is strongly peaked in the forward direction, we can assume

$$\sigma(\phi_1) \simeq \sigma_0 \exp \{-A(1 - \cos \phi_1)\},$$

$$\sigma(\phi_2) \simeq \sigma(\phi_0),$$

and

$$R \simeq u \sec \theta_1,$$

where σ_0 is the differential cross section for $\phi_1=0$ and A is a constant to be so chosen as to fit the experimental angular distribution of the scattered neutrons³¹⁾. Substituting the above approximate equations into the right-hand side of (A.3), we obtain:

$$\Phi_2 = 2 \frac{\Phi_0 \sigma(\phi_0) n^2}{b^2} \frac{2\pi \sigma_0}{A} \{1 - (1 + bt) \exp(-bt)\}. \quad (\text{A.4})$$

Since the measured intensity of the scattered neutrons is proportional to $\Phi_1 + \Phi_2$, the correction factor for the double scattering which should be multiplied to the observed data, is given by:

$$\frac{\Phi_1}{\Phi_1 + \Phi_2} = \frac{1 - \exp(-bt)}{\{1 - \exp(-bt)\} + 4\pi \sigma_0 n \{1 - (1 + bt) \exp(-bt)\} / Ab} \quad (\text{A.5})$$

An example of the numerical data is shown in Fig. 15.

Fig. 15. Example of correction for double scattering ($\theta_1=0^\circ$, $\theta_2=10^\circ$, $\phi_0=170^\circ$). The values for the scatterers used in this measurement are represented by black circles.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN VOL. 13 No. 11 NOVEMBER 1958

The Multiplicity of Mesons Produced in the Nuclear Interaction of High Energy Nucleons and α -Particles in Cosmic Radiation

By Shin-ichi KANEKO*

Institute of Polytechnics, Osaka City University

(Received July 14, 1958)

It was proposed in a previous paper¹⁾ that the multiplicity $n_{\pm}$ of charged mesons produced in the high energy nucleon-nucleon interaction can be empirically expressed as a function of the inelasticity K and the Lorentz factor γ_0 in the center-of-mass system: $n_{\pm} \cong 3.5 K(\gamma_0 - 1)$ for $\gamma_0 \leq 7$, $n_{\pm} \cong 9 K(\gamma_0 - 1)^{1/2}$ for $\gamma_0 \geq 7$. It is shown here that further experimental results published in recent years are also consistent with this dependence. It is also suggested, with the support of experimental material, that the peripheral collision of high energy α -particles with nuclei can be explained in terms of a superposition of a few nucleon-nucleon collisions so that the meson multiplicity in the interaction can also be represented by the above equations. The results of observation of a jet ($3+33_{\pi}$) initiated by a high energy α -particle ($\sim 1.2 \times 10^{13}$ eV/nucleon) are described.

§ 1. Introduction and Summary

It is well known from observations with photographic emulsions that the multiplicity of charged mesons produced in the high energy nucleon-nucleon interactions shows wide fluctuation even for a given primary energy. However, it was shown in our previous paper¹⁾ that the multiplicity normalized at the completely inelastic interaction for individual events seems to be a rather smooth function of primary energy; i.e., the multiplicity is empirically given by

$$n_{\pm} \cong 3.5 K(\gamma_0 - 1) \quad \text{for } 2 \lesssim \gamma_0 \lesssim 7, \quad (1)$$

$$n_{\pm} \cong 9 K(\gamma_0 - 1)^{1/2} \quad \text{for } 7 \lesssim \gamma_0, \quad (2)$$

where $n_{\pm}$, K and γ_0 are the number of charged mesons, the inelasticity, and the Lorentz factor of the incident nucleon in the center-of-mass (C-) system measured for each event, respectively.

Recent observations made at different laboratories seem also to support this dependence as will be shown in § 2. Some possible evidence for this view is discussed in § 3 in regard to an apparent discrepancy between the conclusion given by the Bristol group and ours. In this connection, the validity of the assumption that the transverse momenta of

* Now at the Physics Department, University of Washington, Seattle, Washington, U.S.A. on leave of absence from the Osaka City University.

shower particles have a fairly constant value is also discussed.

The interaction of high energy α -particles (or heavier particles) with nuclei in photographic emulsions has so far been analysed by many authors under the assumption that the event was produced by a single nucleon-nucleon (N-N) interaction. The assumption may be inadequate for analysing the nucleus-nucleus collision, especially the head-on collision, since some of nucleons in both of the nuclei may as a whole interact with each other. In § 4, it is pointed out that at least the peripheral collision of high energy α -particles with nuclei should be explained in terms of a simple superposition of the N-N interactions. The experimental results now available are shown to be in agreement with this prediction. Therefore, it results that the multiplicity of mesons produced in the peripheral collision of α -particles can also be approximately represented by Eqs. (1) and (2) within the present experimental limitations.

The results of observation of a jet ($3+33_\alpha$)*, which gives a support to the argument in § 4, initiated by a high energy α -particle ($\sim 1.2 \times 10^{13}$ eV/nucleon) are described in detail in § 5.

§ 2. Nucleon-Nucleon Interactions

We reproduce in Fig. 1 the relation of $n_\pm/K$ versus r_0-1 (Fig. 1 in reference 1). In drawing this figure, we have supposed that the process of antiproton-nucleon annihilation is equivalent to the N-N collision of $r_0=2$ and $K=1$ as far as we are concerned with the meson multiplicity. This assumption has not yet been proved to be correct on experimental and theoretical grounds. Afterwards, Iizuka *et al.*²⁾ have shown that a simple relation between $n_\pm/K$ and r_0-1 holds still at the energy region of Cosmotron. They have calculated average values of $n_\pm/K$ from the average energies of pions produced in the proton-proton collisions at the Cosmotron energies and have shown that the straight line fitted to these experimental values passes

* This is the conventional nomenclature of the type of shower. The first and the second numbers refer to those of heavily ionizing prongs and secondary relativistic charged particles, respectively. The subscript α (or p) means that the primary particle of the shower is an α -particle (or a singly charged particle).

through the antiproton annihilation point ($\square$ in Fig. 1) with slope 0.78 as shown in Fig. 1. This probably shows that the average energy in the C-system of pions produced in the proton-proton collisions at 6 GeV ($r_0=2$) should be approximately the same as that in the antiproton-nucleon annihilation and hence the above assumption should be correct**.

At extremely high energies, on the other hand, some observations have been done at various laboratories in recent years. The experimental data³⁻⁵⁾ of these showers selected under the similar criteria to reference 1 are shown in Fig. 1 and Table I. It seems to require explanation for the individual events especially for estimates of inelasticity.

Event A-1³⁾: This shower ($1+7_p$) was detected by the tracing back method⁶⁾ and is not a pure proton-proton collision, since a proton ejected backwards with ~ 100 MeV was accompanied. Multiple scattering was satisfactorily measured for five shower particles ejected at large angles with respect to the primary direction. The energy of a neutral pion ejected into the forward cone was determined by measuring energies and angles of two electron pairs. Assuming all the shower particles to be pions, we found that $r_0=13_{-4}^{+6}$ and $K \approx 0.18$.

Event A-2⁴⁾: The average energy of two neutral pions in the C-system of this event was found to be ~ 4.2 GeV. Assuming that the charged mesons were emitted with the same average energy, we can estimate the value of $n_\pm/K$.

Events observed by the Bristol group⁵⁾: Edwards *et al.* have carried out a systematic observation on the transverse momenta, p_T , of secondary particles arising from the energetic nuclear interactions, and have shown that p_T of secondary pions has a rather narrow distribution around 0.5 GeV/c. (The same conclusion, but with a somewhat lower value of the average $\langle p_T \rangle$, has also been

** Note added in proof: By making use of nuclear plates, Kalbach, Lord and Tsao have recently observed that in the proton-proton interaction at 6.2 GeV the average charged pion multiplicity and the average degree of inelasticity are 1.9 ± 0.3 and 0.49 ± 0.05 , respectively. This observation appears to support the above prediction. We are indebted to Prof. J. J. Lord for informing us of their results before publication.

Fig. 1. The normalized multiplicity, the multiplicity divided by the inelasticity, of charged mesons plotted against the kinetic energy (in units of the nucleon rest energy) of the incident nucleon in the center-of-mass system. The chain line is the one given by Iizuka *et al.*²⁾, which has been fitted to three experimental points (marked with dots) and has slope 0.78. The square and the circles are the experimental points already described in the previous paper¹⁾. The solid and the dotted lines represent Eqs. (1) and (2), respectively. The triangles show the experimental results of the proton-induced showers: A-1(1+7_p) observed by Kaneko *et al.*³⁾ and A-2(1+6_p) observed by Fowler⁴⁾. The crosses are those observed by the Bristol group⁵⁾.

obtained by the Japanese group using emulsion cloud chambers⁷⁾.) Assuming that 80 per cent of secondary particles are pions with $p_T=0.5$ GeV/c, they have estimated the inelasticity for 13 jets induced by high energy protons*:

$$K'' = \frac{1.5 p_T \sum \cos \bar{\theta}}{2 \gamma_c}, \tag{3}$$

* We are very much indebted to Drs. D. H. Perkins and J. Iwadare for informing us of the detailed data of these jets.

where $\bar{\theta}$ is the angle of a secondary particle in the C-system. The values of $0.8n_s/K''$ of eleven jets with $N_h < 4$ among them are plotted in Fig. 1, where n_s and N_h are the numbers of shower particles and of heavily ionizing particles, respectively.

§ 3. Discussion of Nucleon-Nucleon Interactions

It can be seen from Fig. 1 that the dotted curve (Eq. (2)) is in excellent agreement with events A-1 and A-2. The Bristol events are also consistent with the curve within factor two except for two events (P-19 and P-20). It should be noted, however, that they indicate the general trend that the events with low multiplicity lie below the curve, whereas those with high multiplicity lie above. It was also shown that the jet with low multiplicity shows a strong angular anisotropy rather than that with high multiplicity. These facts have led the Bristol group to the conclusion that the inelasticity does not appear to be dependent strongly on the multiplicity at a fixed energy. This conclusion contradicts to the dependence given by Eq. (2) that the multiplicity is proportional to the inelasticity at a given energy.

The estimate of K for the events described in our previous paper and events A-1 and A-2 is based upon the direct measurement of energies of secondary particles in the laboratory system and upon the determination of the average energy in the C-system. We have then noticed that all of these data can be well approximated by Eq. (2) in spite of the fact that they were obtained by many different observers. Whereas, the Bristol result relies on the assumption that the average value of transverse momenta is constant for each event. It is to be noted, however, that the assumption $p_T = \text{const.}$ should be valid only in the statistical meaning. Moreover, due to their selection of particles on which the energy measurements were made, a strong bias should be given to the events with high multiplicity. It may therefore be possible that $\langle p_T \rangle$ for individual events depends to some extent upon n_s or it shows fairly large fluctuation from event to event. For example, $\langle p_T \rangle$ computed for the showers analysed in detail by Debenedetti *et al.*⁽⁸⁾ (3+39_p) and Glasser *et al.*⁽⁹⁾ (2+15_p) was 0.34 and 0.07

GeV/c, respectively. As was explained in the previous paper, these showers are in a good agreement with the dotted line in Fig. 1. However, by computing K'' for these showers by Eq. (3) with $p_T = 0.5$ GeV/c, one can see that the resulting value of n_s/K'' for the second shower would then be far from the dotted line, while the first shower would be still consistent with the line. It seems therefore that Eq. (3) with $p_T = 0.5$ GeV/c gives a reliable estimate of the inelasticity only for events with high multiplicity.* These considerations show that it is necessary to accumulate further data of $\langle p_T \rangle$ for individual events especially for those with low multiplicity, in order to prove the statement given by the Bristol group that K does not depend strongly upon n_s at a given energy. At present, it seems more reasonable to suppose that almost all jets analysed in detail are in fact consistent with Eq. (2) so that n_s is proportional to K at a given energy.

§ 4. Interaction of High Energy α -Particle with a Nucleon or the Peripheral Nucleons

We restrict ourselves to the interaction of high energy α -particle with either a nucleon or peripheral nucleons in a target nucleus. This should probably correspond to an α -particle induced shower with $N_h \leq 4$ observed in photographic emulsion. The interaction is assumed to be explained by a simple superposition of single N-N interactions. (This assumption has already been employed by some authors¹⁰⁾ for analysing the interaction of α -particles or heavier nuclei.) A support for the assumption seems to be given by the fact observed by Appa Rao *et al.*¹¹⁾ that the nuclear interactions initiated by cosmic-ray α -particles (median energy ~ 10 GeV/nucleon) can be classified into those in which 0, 1, or 2 protons inside the α -particles have taken part, by observing the number of shower particles ejected within a definite cut-off

* It may be more reasonable to interpret this view in terms of the degree of anisotropy rather than the multiplicity. As stated already, the Bristol result suggests that the multiplicity depends strongly upon the angular anisotropy. If we assume that $\langle p_T \rangle$ for events showing the strong anisotropy is comparatively small, we could obtain not only a satisfactory explanation of the data of the above two showers but also a justification of the dependence given by Eq. (2) (see Eq. (5)).

angle. Furthermore, fragmentation products consisting of nucleons, α -particles, and heavier fragments emerge quite often from collisions of heavy primary particles with emulsion nuclei. These observations show that many nucleons within the incident nucleus do not experience any significant effect from the collision and are simply emitted by a process such as the evaporation from the nucleus in its own system of reference. It is apparent therefore that some of nucleons in an α -particle play a significant role in the collision, but the remaining ones are not concerned with the interaction so that the whole process may be considered as a simple sum of a few N-N collisions. This simple view might, however, seem to be invalid for the central collision of an extremely energetic α -particle with a heavy nucleus, since several nucleons existing behind the first target nucleon in the heavy nucleus come to participate in the interaction, resulting in that only a collision between the incident α -particle and the target particle heavier than a nucleon is responsible for the meson production, and hence the interaction would no longer be a simple superposition of the elementary processes.

It has been shown in the previous section that the normalized multiplicity in the N-N collisions is satisfactorily expressed by Eqs. (1) and (2) with the support of experimental material. If we assume that the peripheral collision of α -particle can be explained in terms of a simple superposition of N-N collisions, then it results in that $n_{\pm}/K$ observed for α -induced showers should also be represented by Eqs. (1) and (2). This is simply due to the proportionality between $n_{\pm}$ and K at a given energy. If we estimate γ_0 and K for an α -induced shower under the assumption that the shower has been produced by a single N-N collision, the resulting values of $n_{\pm}$ and K are of course the sums of those in the elementary processes involved in the interaction so that they are usually greater than those in an N-N collision (The value of K thus estimated can amount to 4 in the upper limit.), but the ratio $n_{\pm}/K$ remains to be the same as that in the latter at the same value of γ_0 .

The normalized multiplicities of three α -induced jets are shown in Fig. 2 and Table I. Shower B-1 is the one observed by us and

is described in detail in § 5. The inelasticity of shower B-2 has not been explicitly given by Gramenitzkij *et al.*¹²⁾ but can be roughly estimated from the angular distribution of shower particles given in their paper by assuming p_T to be constant (see §§ 3 and 5). Shower 12 is the one¹³⁾ used already for the analysis in the previous paper.

Fig. 2. The normalized multiplicity of showers initiated by high energy α -particles plotted against the kinetic energy per nucleon (in units of the nucleon rest energy) of the incident α -particle in the center-of-mass system. The solid and the dotted lines represent Eqs. (1) and (2), respectively. The crosses show the experimental results of the α -particle induced jets: B-1 ($3+33\alpha$) described in § 5; B-2 ($1+37\alpha$) observed by Gramenitzkij *et al.*¹²⁾; 12 ($0+14\alpha$) observed by Ciok *et al.*¹³⁾ The quantity $9(\gamma_0-1)/(\gamma_0 \sin \theta_m) = n_{\pm}/K$ computed for 9 α -induced showers observed by Winkler¹⁰⁾ is shown with dots.

In the lower energy region, the inelasticity in interactions initiated by α -particles was not estimated so far by plausible method; it seems therefore that there are no experimental data to be plotted in Fig. 2. However, we could obtain some knowledge from angular distribution observed in α -particle induced showers. Winkler¹⁰⁾, for example, has presented the maximum angle, θ_m , of shower particles together with the primary energy for 26 α -induced showers. We can estimate, as was explained in the previous paper, the normalized multiplicity as

$$\frac{n_{\pm}}{K} = \frac{9(\gamma_0-1)}{\gamma_0 \sin \theta_m},$$

assuming that pions have been emitted with a single energy in the C-system. The quantity on the right-hand side in the above formula has been computed for 9 showers having $N_h < 4$ and plotted in Fig. 2. (The values of γ_0 estimated by the method of Castagnoli *et al.*¹⁴⁾

for these showers have been employed in this computation.) It is to be noted that the uncertainty in the position of the individual point should be quite large due to possible fluctuations in γ_c and θ_m and to incorrectness of the assumption of the single energy.

It seems that the dotted and the solid lines (Eqs. (2) and (1)) are consistent with experimental points in the higher and the lower energy regions, respectively*. This probably suggests that the peripheral collision of α -particles with nuclei can be explained in terms of a simultaneous occurrence of a few N-N collisions of the same energy. The experimental and statistical precisions for α -induced showers are quite insufficient at present in order to draw any decisive conclusions. But if we confirm the above view to be correct, it turns out that the investigation of α -induced showers is very helpful for studying the single N-N interactions. This is due to the fact that an α -induced jet should in general be subject to a smaller fluctuation in the normalized multiplicity than a proton jet, because the former itself is already a superposition of the latter. It is to be noted, in this connection, that α -induced showers can perhaps be observed with a frequency comparable with proton-induced showers in the stacks exposed at an altitude higher than 30 km, and also that much more peripheral collisions should occur for incident α -particles rather than for protons¹⁵⁾.

Furthermore, it seems possible to give some indication of the number of interacting nucleons in the incident α -particle. Edwards *et al.*⁶⁾ have observed three α -induced jets and six proton-jets with $N_h < 3$ in the energy interval 2,000~5,000 GeV/nucleon (Fig. 1 in their paper). The average multiplicity for these proton-jets is found to be ~ 10 (which gives the average inelasticity in the N-N collision in this energy region to be $\sim 1/5$ with the aid of Fig. 1), whereas it amounts to ~ 30 for the α -jets. This seems to suggest, although the statistical precision is quite low, that on the average three nucleons in the incident α -particle come to interact during the peripheral collision. At the lower energies (~ 100 GeV/nucleon), on the other hand, the

ratio of average multiplicity between α - and proton-induced showers (irrespective of N_h) was found to be about 1.3 by Engler *et al.*¹⁶⁾ and Winkler¹⁰⁾. It seems that this value gives a lower estimate, since in this energy region proton-showers with low N_h and n_s are likely to escape from observation and the correction made for their frequency seriously affects the result. Indeed, the average number of nucleons taking part in collisions (including central collisions) has been estimated to be 2.4 by Appa Rao *et al.*¹¹⁾ in a quite different but more reasonable manner**. This should be compared with the above value at the higher energies allowing for the fact that the former refers to all values of N_h but the latter to $N_h < 3$.

§ 5. Observation of Jet B-1 (3+33_a)

Event B-1, as well as A-1, was detected in a large stack (108 sheets of 6'' $\times$ 9'' size) of 600 microns thick G5 stripped emulsions exposed at 29 km altitude during six hours in Japan. Shower particles consist of 14 and 19 tracks in the inner and the outer cones, respectively. The shower axis has length 6.5 mm per plate and passes through 13 plates. Except for three, all the secondary shower tracks have been carefully traced from plate to plate (total length ~ 240 cm), and only one nuclear interaction (2+13_p) could be found. This observation corresponds to an extreme case improbable to occur, if we assume the mean free path for interaction of shower particles to be geometrical (~ 35 cm) and also take into account some neutral particles involved in the inner cone.

The target diagram of the shower particles in the laboratory system is shown in Fig. 3. The primary energy of the incident α -particle is estimated by the method of Edwards *et al.*⁶⁾ assuming that the jet has been initiated by a single N-N collision:

$$-2 \log \gamma_c = \langle \log \tan \theta \rangle_f + \langle \log \tan \theta \rangle_b, \quad (4)$$

where θ is the laboratory angle of a shower particle with respect to the primary direction and both of the terms on the right-hand side are the averages taken for the forward and the backward cones respectively. Thus, we

* Note added in proof: In addition, the Bristol event $\alpha-5(0+11_a, \gamma_a=108, K'=0.105)$ agrees fairly well with the dotted line.

** By using a simple model for the nuclear interaction of α -particles, Ceccarelli *et al.*¹⁶⁾ have shown that the average number of interacting nucleons is calculated to be 2.8.

Fig. 3. The target diagram of the shower particles in the laboratory system of jet B-1 (3+33_a): (a) the inner cone, (b) the outer cone. The six white circles correspond to the particles excluded for estimating the inelasticity (see the text).

obtain $\gamma_0 = 76_{-23}^{+88}$; i.e., the primary energy of the incident α -particle is estimated to be $(1.2_{-0.6}^{+1.2}) \times 10^{13}$ eV/nucleon.

An estimate of the inelasticity of the interaction will be most easily given by making the assumption of $p_T = \text{const}$. The high multiplicity of the shower particles in this event should justify to make this assumption (see § 3). Using Eq. (3) with $p_T = 0.5$ GeV/c, the normalized multiplicity is then written as

$$\frac{n_{\pm}}{K} = \frac{2\gamma_0}{1.5 p_T \langle \csc \bar{\theta} \rangle} = \frac{2.7 \gamma_0}{\langle \csc \bar{\theta} \rangle}. \quad (5)$$

In Fig. 4 is shown the distribution in $\csc \bar{\theta}$

of the shower particles which have been transformed by the relation usually employed:

$$\csc \bar{\theta} = \frac{1 + \gamma_0^2 \tan^2 \theta}{2\gamma_0 \tan \theta}.$$

In addition to those shown in Fig. 4, there are four particles having very large values of $\csc \bar{\theta}$. If we assume that these particles are pions with $p_T = 0.5$ GeV/c, their values of Lorentz factor in the C-system would be too high as compared with the value of γ_0 ; this is inconsistent with the fact that none of the shower particles was ejected into the backward direction in the laboratory system. They should therefore be either the pions having $p_T \ll 0.5$ GeV/c or the particles heavier than the pion.

Fig. 4. The distribution in $\csc \bar{\theta}$ of 29 shower particles of jet B-1, where $\bar{\theta}$ is the angle of a shower particle in the center-of-mass system with respect to the primary direction. The shaded histogram shows the particles ejected into the forward cone. Two particles represented by the dotted squares, together with four particles having the values of $\csc \bar{\theta}$ too high to be shown in the figure, are discarded for estimating the inelasticity.

Two particles among those shown in Fig. 4 have also the values of $\csc \bar{\theta}$ much higher than the others. They appear to be similar to the four particles mentioned above. Of these six particles showing the higher values of $\csc \bar{\theta}$, two being in the forward cone may be two protons initially involved in the incident α -particle. It is remembered, in this connection, that at the lower energies a non-interacting proton in an incident α -particle emerges within an extremely small angle relative to the primary direction¹¹⁾. In the present event, however, either of the two tracks may be such a non-interacting proton,

but the other cannot be, since the relative momentum between them in the transverse direction would be computed to be too high ($\sim 5 \text{ GeV}/c$) assuming that their energy is the same as that at incidence. Whereas, the remaining four out of the six particles are in the backward cone and may consist of the colliding partners and the shower particles produced in the secondary interaction inside the target nucleus. (The existence of three heavy prongs accompanied by the jet suggests that some of the shower particles in the outer cone might have been originated from the secondary interaction.)

Fig. 5. The angular distribution of the shower particles in the center-of-mass system of jet B-1. The dotted area corresponds to the six shower particles discarded for computing the inelasticity.

With the exception of these six particles, it results in that the average values $\langle \csc \bar{\theta} \rangle$ for the forward and the backward cones agree quite well with each other. The normalized multiplicity is therefore estimated to be 64 using Eq. (5).

The angular distribution of the shower particles in the C-system is strongly peaked at the forward and the backward directions as shown in Fig. 5.

Acknowledgments

The author wishes to express his sincere thanks to Prof. Y. Watase for his interest and kind encouragement. Thanks are due to Mr. S. Matsumoto for helpful discussion and criticism during the course of the work. He is also indebted to Prof. M. Okazaki and Mr. O. Kusumoto for valuable advice, and to Prof. S. Hayakawa for reading the manuscript.

The emulsion stack used in the work has been provided, exposed, and processed with

the cooperative efforts of the members of the Japanese emulsion group under the auspices of the Institute for Nuclear Study, University of Tokyo. The author should like to take this opportunity of thanking the members of the group and the staff of the Institute, especially Profs. S. Kikuchi, O. Minakawa, and J. Nishimura.

The work has been supported in part by a Grant-in-Aid for Fundamental Scientific Research from the Ministry of Education.

On the Theory of the Brownian Motion

By Morikazu TODA

*Department of Physics, Tokyo University of Education,
Tokyo, Japan*

(Received August 1, 1958)

The Brownian motion of an oscillator in a thermostat is considered assuming simple forms of interaction between them. No further assumption is made except that the thermostat is always in thermal equilibrium in itself. Solving the Liouville equation or its counterpart in quantum mechanics the long time evolution of the system is clarified. Thus the theory connects automatically the irreversible and the equilibrium behaviors of the system without any ad hoc assumption as in conventional theories. The results include, as a special case, the equation derived by Kramers and Chandrasekhar using the theory of stochastic processes. It is shown that the oscillating part of the distribution function or the density matrix plays an important role to which the peculiar way of damping of the oscillator is to be attributed.

§ 1. Introduction

The purpose of this paper is to treat the problem of the Brownian motion in the framework of the general statistical mechanics of irreversible processes developed quite recently. While the latter deals with a large system in which irreversible processes themselves take place, the former pays special attention to a small system or a particle embedded under the supposition that the rest of the system stays always in thermal equilibrium playing the role of a thermostat. With the thermostat included, the problem of the Brownian motion reduces to a very special case in the general statistical mechanics of irreversible processes in which the initial condition is that only a small number of freedoms is out of equilibrium. The interaction within the thermostat will guarantee the state of equilibrium for it.

Though there exists a number of theories of the Brownian motion, most of them are based on the theory of random flights or of stochastic processes¹⁾ and are rather phenomenological in nature. The coefficients in the Fokker-Planck equation, for instance, are left unknown, though certain relations among them are found by other considerations such as the requirement of the state of equilibrium to which the whole system has to approach. The same can be said with respect to the Langevin equation, in which one assumes the friction constant and the correlation constant of the fluctuating part of the force acting on

the particle under consideration. The relation between these two constants is left unknown till one demands that the asymptotic solution ought to be the Maxwell-Boltzmann distribution law. Thus the theory is usually supplemented artificially to meet the request of the statistical mechanics of the equilibrium state.

From the microscopic point of view the friction constant and correlation constant are to be derived from the interaction between the particle and the thermostat. Moreover one has to show the force due to the thermostat can be split out in two parts, the friction and the random forces, as is done in the Langevin equation. An attempt in this direction is seen in one of the papers by Kirkwood²⁾, in which the friction force is attributed to the plateau value of a certain quantity. Actually he intended to formulate the equation which had been derived by Kramers and Chandrasekhar¹⁾ using the theory of stochastic processes. The validity of the time-smoothing procedure employed in the theory of Kirkwood, together with the existence of the plateau value, however, remain to be justified.

There is another kind of microscopic theories in which one calculates the transition probability from a state to another, and thus formulates the so-called Pauli's equation in quantum mechanical terminology. If one is concerned only with the diagonal elements in the representation in which the unperturbed state is diagonal, it is clear that one gets some

equation different from that of Chandrasekhar and quite different evolution to equilibrium.^{3),4)}

As we shall see later we can formulate this kind of theory including the off-diagonal elements and clarify that it is still insufficient to describe the detailed behavior of the system.

Recently we have developed the general statistical mechanics of irreversible processes⁶⁾ which is quite transparent in mathematical manipulations and affords direct application to concrete problems. In this paper we shall use this method to provide us with a consistent theory of the Brownian motion.

As the essential feature of the problem of the Brownian motion is to ask the behavior of a small system under the influence of the thermostat, we treat an oscillator which interacts by a certain simple interaction with the thermostat, which we assume to consist of a large number of harmonic oscillators. In §2 we shall derive equations which are purely mechanical and are applied in the following sections. In §3 we shall use the solution of the Liouville equation obtained from the general theory⁶⁾. Assuming a simple form of interaction we get the Kramers equation, a kind of diffusion equation in phase space. Other kinds of interaction are examined. It is shown that if the interaction is proportional to the displacement of the oscillator one gets the Langevin friction and that if it is proportional to the momentum one gets the Lozentz friction. The latter is what we meet in the problem of a charged particle in a radiation field, that is the problem of radiation damping. In §4 analogous treatments for quantum mechanical case are performed.

In §5 we derive the average equation of motion with friction in one step. In §6 an extension to forced oscillation with application to the problem of stopping power is given. §7 is devoted to clarify the origin of the discrepancy between the result of Chandrasekhar

and that of Zwanzig⁴⁾. It is shown that the exact interpretation of the latter has to be expressed in terms of the so-called systematic part of the density matrix or the distribution function. The important role of the remaining terms, oscillating terms, is stressed in this connection.

In this paper we do not make explicit use of the so-called diagonal singularity condition stated by van Hove⁵⁾ and used in our general statistical mechanics, because this condition is to do with large systems, the thermostat in our present case. The state of thermal equilibrium of the thermostat is maintained by this condition.

§2. Mechanical Equations in Classical Case

To treat the problem rigorously we have to define a system, simple as possible but relevant of real situations. Most of the systems we can treat with rigour can be regarded as composed of harmonic oscillators. Therefore we shall consider a system of harmonic oscillators to clarify the fundamental nature of the Brownian motion. In so doing little of the general feature of the problem will be lost. Our model is then as follows: a harmonic oscillator, the motion of which is under consideration, is interacting with a large system composed of a great number of harmonic oscillators. The latter is afterwards assumed to be in thermal equilibrium and serves as a thermostat. We can also extend our treatment to the case where there is an external force depending on time; but we shall omit it for a while.

We denote by x , p and m the coordinate, the momentum and the mass of the oscillator under Brownian motion, and by x' , p' and m' the coordinates, the momenta and the masses of oscillators of the thermostat. The energy of the total system is then

$$\mathcal{H} = H^0(x, p) + H'(x', p') + \lambda V(x, p; x', p') \quad (2.1)$$

with

$$H^0(x, p) = \frac{1}{2m} p^2 + \frac{1}{2} m \omega^2 x^2, \quad (2.1')$$

$$H'(x', p') = \sum_j \left(\frac{1}{2m'} p_j'^2 + \frac{1}{2} m' \omega_j'^2 x_j'^2 \right) \quad (2.1'')$$

where H^0 represents the energy of the central oscillator with the frequency ω , and H' that

of the thermostat, and λV the interaction between them, λ being the coupling constant assumed to be small.

The Liouville equation for the distribution function $\rho(x, p; x', p')$ of the total system is

$$\frac{\partial \rho}{\partial t} = [\mathcal{H}, \rho], \quad (2.2)$$

where we have used the notation for the Poisson bracket. We may use the Liouville operators defined as

$$L^0 \rho = [H^0 + H', \rho], \quad (2.2')$$

$$L^1 \rho = [V, \rho]. \quad (2.2'')$$

We make use of a suitable transformation and rewrite (2.2) in the form:

$$\frac{\partial \rho_t}{\partial t} = \lambda [V_t, \rho_t]. \quad (2.3)$$

As we will make use of the explicit forms of the transformed quantities in the next section, we shall write down some of them. The transformation which brings (2.2) into (2.3) is

$$\rho \rightarrow \rho_t = e^{-tL^0} \rho, \quad L \rightarrow L_t = L(x_t, p_t), \quad \text{etc.}$$

Any quantity F which does not depend on time explicitly is transformed at the same time into F_t , where

$$\partial F_t / \partial t = -L_t^0 F_t. \quad (2.4)$$

Especially

$$\begin{aligned} dx_t/dt &= -L_t^0 x_t = -\left(\frac{\partial H^0(x_t, p_t)}{\partial x_t} \frac{\partial}{\partial p_t} - \frac{\partial H^0(x_t, p_t)}{\partial p_t} \frac{\partial}{\partial x_t} \right) x_t \\ &= p_t/m. \end{aligned} \quad (2.5)$$

Further

$$dp_t/dt = -L_t^0 p_t = -m\omega^2 x_t. \quad (2.6)$$

Thus x_t satisfies the differential equation

$$d^2 x_t / dt^2 + \omega^2 x_t = 0. \quad (2.7)$$

Solving the last equation with the initial condition that

$$t=0: \quad x_t = x, \quad p_t = p,$$

we get

$$x_t = x \cos \omega t + (p/m\omega) \sin \omega t. \quad (2.8)$$

Similarly

$$p_t = p \cos \omega t - m\omega x \sin \omega t. \quad (2.8')$$

It must be noted that the oscillating nature of these quantities comes from the fact that the eigen-values of the operator L^0 are purely imaginary. The operator $\exp -tL^0$ gives thus oscillating behavior to the quantities transformed. At the same time one notes that the transformation is merely a rotation of the coordinate axes; the angle of rotation being a function of time.

It is convenient to introduce an arbitrary function $F(x, p)$ which is a function of the coordinate and the momentum of the oscillator and does not depend on time explicitly. Its average is

$$\langle F \rangle = \iint F \rho \, d\tau \, d\tau' \tag{2.9}$$

where

$$d\tau = dx \, dp, \quad d\tau' = dx' \, dp' = \prod_j dx'_j \, dp'_j.$$

We may write it referring to the coordinate system (x_i, p_i) in such a way that

$$\langle F \rangle = \iint F_i \rho_i \, d\tau_i \, d\tau'_i, \quad d\tau_i = dx_i \, dp_i, \text{ etc.}$$

We multiply F to the both sides of (2.2) to get

$$\iint F \frac{\partial \rho}{\partial t} \, d\tau \, d\tau' - \iint FL^0 \rho \, d\tau \, d\tau' = \lambda \iint FL^1 \rho \, d\tau \, d\tau'. \tag{2.10}$$

The right hand side of this equation can be written as

$$\mathcal{F} \equiv \lambda \iint FL^1 \rho \, d\tau \, d\tau' = \lambda \iint F_i L_i^1 \rho_i \, d\tau_i \, d\tau'_i. \tag{2.10'}$$

§ 3. Statistical Behavior of the System

We shall solve the equation

$$d\rho_i/dt = \lambda [V_i, \rho_i] \tag{3.1}$$

assuming that λ is sufficiently small. We have to know the long-time evolution of the system, and this requires some special technique. We first observe that if $\lambda=0$, then ρ_i remains constant all the time. Whereas when λ does not vanish, but is small, ρ_i will approach slowly to equilibrium value, although there is fluctuation always. So we may split ρ_i in two parts: the one is the systematic part $\bar{\rho}$, which is to approach to equilibrium value, being governed by some sort of master equation. The other is the fluctuating part, which is zero if $\lambda=0$, and can be expanded in powers of λ . It is then convenient to look the fluctuating part as a function of $\bar{\rho}$ and t . That is, we assume the form

$$\rho_i = \bar{\rho} + \lambda P(\bar{\rho}, t) + \lambda^2 Q(\bar{\rho}, t) + \cdots. \tag{3.2}$$

If $\lambda=0$, it is again evident that $d\bar{\rho}/dt$ vanishes, indicating the expansion

$$d\bar{\rho}/dt = \lambda \varphi(\bar{\rho}) + \lambda^2 \psi(\bar{\rho}) + \cdots, \tag{3.3}$$

in which we have used the fact that we can define the systematic part in such a way that the rate of change in $\bar{\rho}$ is determined by the value of $\bar{\rho}$ at that time. This implies that $d\bar{\rho}/dt$ and $\varphi, \psi, \cdots$ are independent of time and are functions of $\bar{\rho}$ itself. We can decide $\varphi, P, \psi, Q, \cdots$ in the following manner. We insert (3.2) and (3.3) into (3.1), and get, as the first power of λ ,

$$\varphi + \partial P / \partial t = [V_i, \bar{\rho}]. \tag{3.4}$$

For the derivative $\partial P / \partial t$ in (3.4) $\bar{\rho}$ is regarded as if it were a constant. The term $(\partial P / \partial \bar{\rho}) d\bar{\rho} / dt$ is of higher order.

To determine φ and P from this single equation we assert, as mentioned above, that φ is a function of $\bar{\rho}$ and does not depend on time explicitly. This kind of requirement on $\bar{\rho}$ is sufficient to determine the systematic part and the master equation for this. Consequently

it may be said that $F, Q, \dots$ represent oscillating behavior of the system around the smooth path $\bar{\rho}(t)$. The role of the oscillating part will be elucidated in the following calculation.

We have noticed that in general V_t oscillates with time. If the time average of V_t does not vanish and depends on the energy of the oscillator, it gives small shift of the frequency or the energy of the oscillator. In principle we can get rid of this term by a small shift of the origin of the energy and a small shift of the potential of the oscillator.* We may safely assume that $\varphi=0$.**

We make use of a converging factor, and obtain

$$P(\bar{\rho}, t) = \lim_{s \rightarrow 0} \left[\int_{-\infty}^t e^{s t_1} V_{t_1} dt_1, \bar{\rho} \right]. \quad (3.5)$$

Inserting the expansion (3.2) into the right side of (2.10), we get

$$\mathcal{F} = \lambda \iint F_t L_t^{-1} \bar{\rho} d\tau_t d\tau_{t'} + \lambda^2 \iint F_t L_t^{-1} P(\bar{\rho}, t) d\tau_t d\tau_{t'}. \quad (3.6)$$

We assume that the thermostat is in equilibrium. This implies that the coordinates and the momenta of the oscillators in the thermostat are distributed randomly obeying the Maxwell-Boltzmann distribution law. The integral

$$\int L_t^{-1} \bar{\rho} d\tau_{t'} = \int [V_t, \bar{\rho}] d\tau_{t'}$$

represents the shift of the potential of the central oscillator as mentioned above. We can omit, therefore, the first term in (3.6). We have

$$\begin{aligned} \mathcal{F} &= \lambda^2 \iint F_t L_t^{-1} P d\tau_t d\tau' \\ &= \lambda^2 \iint F(x_t, p_t) \left\{ \left(\frac{\partial V_t}{\partial x_t} \frac{\partial P}{\partial p_t} - \frac{\partial V_t}{\partial p_t} \frac{\partial P}{\partial x_t} \right) + \sum_j \left(\frac{\partial V_t}{\partial x_{tj'}} \frac{\partial P}{\partial p_{tj'}} - \frac{\partial V_t}{\partial p_{tj'}} \frac{\partial P}{\partial x_{tj'}} \right) \right\} d\tau_t d\tau_{t'}. \end{aligned}$$

The second term including the Poisson bracket with respect to the thermostat vanishes after partial integration. Thus

$$\begin{aligned} \mathcal{F} &= + \lambda^2 \iint F(x_t, p_t) \left(\frac{\partial V_t}{\partial x_t} \frac{\partial P}{\partial p_t} - \frac{\partial V_t}{\partial p_t} \frac{\partial P}{\partial x_t} \right) d\tau_t d\tau_{t'} \\ &= - \lambda^2 \iint \left(\frac{\partial F_t}{\partial p_t} \frac{\partial V_t}{\partial x_t} P - \frac{\partial F_t}{\partial x_t} \frac{\partial V_t}{\partial p_t} P \right) d\tau_t d\tau_{t'}. \end{aligned} \quad (3.7)$$

To carry out further calculation we shall first assume the case:

$$V = x \sum_j x_{j'}, \quad (3.8)$$

where we have omitted the interaction within the thermostat, which does not seem to be quadratic. Because if it were quadratic the total system would afford many constants of motion, which are in contradiction with the requirement on the irreversibility. In our case this is out of question: the thermostat is playing the role of the source of the random force on the oscillator in question, and that is all. In the special case expressed by (3.8) we get (using invariant property of the Poisson bracket) from (3.7) and (3.5)

* The energy shift corresponds to the first order perturbation due to the interaction λV , which is $\lambda V_0(J)$ in terms of the expansion coefficient in (7.12) below. See also the detailed analysis by I. Prigogine & F. Henin¹⁰⁾, and, for the quantum mechanical case, I. Prigogine & M. Toda⁹⁾.

** ψ does not vanish (diagonal singularity condition), yielding (7.9) or (7.22) below.^{9), 8), 10)}

$$\mathcal{F} = -\lambda^2 \lim_{s \rightarrow 0} \int_{-\infty}^t e^{s(t_1-t)} dt_1 \iint \frac{\partial F_t}{\partial p_t} \left\{ \left(\frac{\partial V_{t_1}}{\partial x_t} \frac{\partial \bar{\rho}}{\partial p_t} - \frac{\partial \bar{\rho}}{\partial x_t} \frac{\partial V_{t_1}}{\partial p_t} \right) + \sum_j \left(\frac{\partial V_{t_1}}{\partial x_{tj'}} \frac{\partial \bar{\rho}}{\partial p_{tj'}} - \frac{\partial \bar{\rho}}{\partial x_{tj'}} \frac{\partial V_{t_1}}{\partial p_{tj'}} \right) \right\} \sum x_{tk'} d\tau_t d\tau_{t'} . \quad (3.9)$$

We note that (see Eq. (2.5))

$$\left. \begin{aligned} x_{t_1} &= x_t \cos \omega(t_1-t) + (p_t/m\omega) \sin \omega(t_1-t) , \\ x_{t_1j'} &= x_{tj'} \cos \omega_j'(t_1-t) + (p_{tj'}/m'\omega_j') \sin \omega_j'(t_1-t) . \end{aligned} \right\} \quad (3.10)$$

Integrating partially we get thus

$$\begin{aligned} \mathcal{F} &= \lambda^2 \lim_{s \rightarrow 0} \int_{-\infty}^0 e^{s\theta} d\theta \left\{ \iint \bar{\rho} \frac{\partial F_t}{\partial p_t^2} \cos \omega\theta \sum_j (x_{tj'} \cos \omega_j'\theta + (p_{tj'}/m'\omega_j') \sin \omega_j'\theta) \sum_j x_{k'} \right. \\ &\quad - \iint \bar{\rho} \frac{\partial^2 F_t}{\partial x_t \partial p_t} \frac{\sin \omega\theta}{m\omega} \sum (x_{tj'} \cos \omega_j'\theta + (p_{tj'}/m\omega_j') \sin \omega_j'\theta) \sum x_{k'} \\ &\quad \left. - \iint \bar{\rho} \frac{\partial F_t}{\partial p_t} (x_t \cos \omega\theta + (p_t/m\omega) \sin \omega\theta) \sum \frac{1}{m'\omega_j'} \sin \omega_j'\theta \right\} . \end{aligned}$$

Integrals with respect to $\theta = t_1 - t$ yield terms like

$$\left. \begin{aligned} \lim_{s \rightarrow 0} \int_{-\infty}^0 e^{s\theta} d\theta \cos \omega\theta \cos \omega'\theta &= \frac{\pi}{2} \{ \delta(\omega + \omega') + \delta(\omega - \omega') \} , \\ \lim_{s \rightarrow 0} \int_{-\infty}^0 e^{s\theta} d\theta \sin \omega\theta \cos \omega'\theta &= \frac{\pi}{2} \{ -\delta(\omega + \omega') + \delta(\omega - \omega') \} . \end{aligned} \right\} \quad (3.11)$$

The integral of $\sin \omega\theta \cos \omega'\theta$ will never give rise to large contribution compared to the above integrals. Consequently $((x_j' x_{k'})_t = x_{tj'} x_{tk'}$ etc.)

$$\mathcal{F} = \lambda^2 \sum_j \frac{\pi}{2} \delta(\omega - \omega_j') \iint \left(\frac{\partial^2 F_t}{\partial p_t^2} \sum (x_j' x_{k'})_t + \frac{\partial^2 F_t}{\partial p_t \partial x_t} \sum \frac{(p_j' x_{k'})_t}{mm'\omega^2} - \frac{\partial F_t / \partial p_t}{mm'\omega^2} p_t \right) \bar{\rho} d\tau_t d\tau_{t'} . \quad (3.12)$$

The assumption that the thermostat is in equilibrium implies that $\bar{\rho}$ factorizes:

$$\bar{\rho} = \bar{f}(x, p) \bar{\rho}_{th}(x', p') , \quad (3.13)$$

and

$$\int (x_j' x_{k'})_t \bar{\rho}_{th} d\tau_{t'} = (kT/m'\omega_j'^2) \delta_{j,k} , \quad (3.14)$$

$$\int (x_j' p_{k'})_t \bar{\rho}_{th} d\tau_{t'} = 0 . \quad (3.14')$$

We assume that there are

$$D\omega'^2 d\omega' / (2\pi)^3 \quad (3.15)$$

oscillators in the thermostat which have the frequency between ω' and $\omega' + d\omega'$, where D is a constant. Finally we come back to the original representation (x, p) , and define

$$f(x, p) = \int \rho(x, p; x', p') d\tau' , \quad (3.16)$$

where we have to notice the fact that while $\bar{\rho}$ factorizes, ρ does not. This is a situation which have never been stated clearly. The difference between ρ and $\bar{\rho}$ is λP . Neglecting higher powers of λ we get the final equation for $\mathcal{F}$.

$$\begin{aligned}\mathcal{F} &= \lambda^2 \frac{\pi}{2} \frac{D}{(2\pi)^3} \frac{1}{mm'} \iint \left(mkT \frac{\partial^2 F}{\partial p^2} - \frac{\partial F}{\partial p} p \right) f dx dp \\ &= \zeta \iint F \frac{\partial}{\partial p} \left(mkT \frac{\partial f}{\partial p} + pf \right) dx dp ,\end{aligned}\quad (3.17)$$

where

$$\zeta = \lambda^2 \frac{\pi}{2} \frac{D}{(2\pi)^3} \frac{1}{mm'} . \quad (3.18)$$

Thus (2.10) takes the form

$$\begin{aligned}\iint F (\partial f / \partial t) dx dp + \iint F \left(\frac{p}{m} \frac{\partial f}{\partial x} - m\omega^2 x \frac{\partial f}{\partial p} \right) dx dp \\ = \zeta \iint F \frac{\partial}{\partial p} \left(mkT \frac{\partial f}{\partial p} + pf \right) dx dp + O(\lambda^3) .\end{aligned}\quad (3.19)$$

As the function F is quite arbitrary we get the following differential equation for the distribution function f for the oscillator.

$$\frac{\partial f}{\partial t} + \frac{p}{m} \frac{\partial f}{\partial x} - m\omega^2 x \frac{\partial f}{\partial p} = \zeta \frac{\partial}{\partial p} \left(mkT \frac{\partial f}{\partial p} + pf \right) . \quad (3.20)$$

This is nothing but the Kramers-Chandrasekhar equation. It is easy to see that the same equation can be obtained for the case in which the interaction between the oscillator and the thermostat is $V = x \sum b_j' / m' \omega_j'$. Thus the Kramers equation is verified from the first principle.

We shall close this section with a comment that if the interaction is of the form either $V = p \sum x_j'$ or $V = p \sum p_j' / m' \omega_j'$ we get, instead of (3.20), the equation

$$\frac{\partial f}{\partial t} + \frac{p}{m} \frac{\partial f}{\partial x} - m\omega^2 x \frac{\partial f}{\partial p} = \zeta' \frac{\partial}{\partial x} \left(\frac{kT}{m} \frac{\partial f}{\partial x} + \omega^2 x f \right) , \quad (3.21)$$

with

$$\zeta' = \lambda^2 \frac{\pi}{2} \frac{D}{(2\pi)^3} \frac{m^2}{m'} . \quad (3.22)$$

This equation can be obtained immediately from (3.20) by rotating the (x, p) coordinate system $-\pi/2$, that is, by changing the variables from $x\sqrt{m\omega/2}$ and $p/\sqrt{2m\omega}$ to $-p/\sqrt{2m\omega}$ and $x\sqrt{m\omega/2}$.

For a charged oscillator interacting with a radiation field

$$\lambda^2 = \frac{4\pi}{3} \left(\frac{e}{m} \right)^2 , \quad D = 8\pi/c^3 , \quad m' = 1 . \quad (3.23)$$

So that $\zeta' = 2e^2/3c^3$.

§ 4. Quantum Mechanical Case

Calculation in the quantum mechanical case goes nearly in parallel to those of § 2 and § 3. One gets formulas in which the Poisson brackets are replaced by the corresponding commutators. We shall show briefly what happens here.

The Liouville equation for the density matrix ρ is

$$d\rho/dt = [\mathcal{H}, \rho] , \quad (4.1)$$

with

$$[\mathcal{H}, \rho] = (i/\hbar)(\mathcal{H}\rho - \rho\mathcal{H}) .$$

By the transformation matrix U , which satisfies the equation

$$-i\hbar \partial U / \partial t = (H^0 + H')U, \quad (4.2)$$

quantities are transformed in such a way that

$$\rho \rightarrow \rho_t = U \rho U^{-1}, \quad V \rightarrow V_t = U V U^{-1}. \quad (4.3)$$

And the Liouville equation takes the form

$$d\rho_t/dt = \lambda[V_t, \rho_t]. \quad (4.4)$$

One sees readily that the operators x_t and p_t satisfy the same forms of operator equations as (2.8) to (2.8').

The average of an arbitrary quantity F is now

$$\langle F \rangle = \text{Tr}(F\rho). \quad (4.5)$$

The time-rate of change of $\langle F \rangle$ is given by the equation

$$\frac{d}{dt} \text{Tr}(F\rho) - \text{Tr}(F[H^0 + H', \rho]) = \lambda \text{Tr}(F[V, \rho]) \equiv \mathcal{F}. \quad (4.6)$$

We write as before $\rho_t = \bar{\rho} + \lambda P(\bar{\rho}, t) + \dots$, and get the same expression for $P(\bar{\rho}, t)$ as (3.5). Inserting $\rho_t = \bar{\rho} + \lambda P(\bar{\rho}, t)$ into the right hand side of (4.6) and dropping the term proportional to λ as we have done in § 3, we get

$$\mathcal{F} = -\frac{\lambda^2}{i\hbar} \text{Tr}\{(F_t V_t - V_t F_t)P\}. \quad (4.7)$$

We treat the case, as before, in which the interaction between the oscillator and the thermostat is $V = xX(x', p')$ omitting the interaction within the thermostat. In virtue of the relation

$$Fx - xF = (\hbar/i)\partial F/\partial p, \quad (4.8)$$

we get

$$\begin{aligned} \mathcal{F} &= -\lambda^2 \text{Tr}\left(\frac{\partial F_t}{\partial p_t} X_t P\right) \\ &= -\lambda^2 \text{Tr}\left(\frac{\partial F_t}{\partial p_t} X_t \int_{t_1}^t [V_{t_1}, \bar{\rho}] dt_1\right) \\ &= \frac{\lambda^2}{i\hbar} \int_{t_1}^t dt_1 \text{Tr}\left\{\left(\frac{\partial F_t}{\partial p_t} x_{t_1} X_{t_1} X_{t_1} - x_{t_1} \frac{\partial F_t}{\partial p_t} X_{t_1} X_{t_1}\right) \bar{\rho}\right\}. \end{aligned} \quad (4.9)$$

In the representation in which the unperturbed energy ($\lambda=0$) is diagonal, we denote by n and N the eigen-states of the oscillator and the thermostat, and write (N stands for $N(\omega, j')$)

$$\left(\frac{\partial F_t}{\partial p_t} x_{t_1}\right)_{n,l} = \left(\frac{\partial F_t}{\partial p_t}\right)_{n,l+1} x_{l+1,l} e^{i\omega(t_1-t)} + \left(\frac{\partial F_t}{\partial p_t}\right)_{n,l-1} x_{l-1,l} e^{-i\omega(t_1-t)}, \quad (4.10)$$

$$(X_t X_{t_1})_{N,N} = |X_{N,N+1}|^2 e^{i\omega(t_1-t)} + |X_{N,N-1}|^2 e^{-i\omega(t_1-t)}. \quad (4.11)$$

We have also the corresponding equations for $x_{t_1} \partial F_t / \partial p_t$ and $X_{t_1} X_t$. We have assumed that the only elements which do not vanish are $X_{N,N\pm 1}$ or $X_{N\pm 1,N}$. We have taken the diagonal elements with respect to the thermostat, because we are dealing with the case in which the thermostat is in equilibrium, and the systematic part of the density matrix factorizes as (3.4), in which $\bar{\rho}_{t_1}$, the density matrix for the thermostat, is diagonal.

We perform the integration with respect to t_1 , obtaining

$$\mathcal{F} = \frac{i}{\hbar} \sum \left\{ \frac{(\partial F_t / \partial p_t)_{n, l+1} x_{l+1, l} |X_{N, N+1}|^2 - x_{l, n, n-1} (\partial F_t / \partial p_t)_{n-1, l} |X_{N, N-1}|^2}{s + i(\omega + \omega')} \right. \\
+ \frac{(\partial F_t / \partial p_t)_{n, l-1} x_{l-1, l} |X_{N, N+1}|^2 - x_{l, n, n+1} (\partial F_t / \partial p_t)_{n+1, l} |X_{N, N-1}|^2}{s - i(\omega - \omega')} \\
+ \frac{(\partial F_t / \partial p_t)_{n, l+1} x_{l+1, l} |X_{N, N-1}|^2 - x_{l, n, n-1} (\partial F_t / \partial p_t)_{n-1, l} |X_{N, N+1}|^2}{s + i(\omega - \omega')} \\
\left. + \frac{(\partial F_t / \partial p_t)_{n, l-1} x_{l-1, l} |X_{N, N-1}|^2 - x_{l, n, n+1} (\partial F_t / \partial p_t)_{n+1, l} |X_{N, N+1}|^2}{s - i(\omega + \omega')} \right\} \bar{\rho}_{l, n; N, N}.$$

We make use of the relation

$$\frac{1}{s + ix} = \pi \delta(x) - i(1/x)_P. \quad (4.12)$$

The second term gives rise to the energy shift which corresponds to the second order perturbation. We may ignore it as before. We assume

$$|X_{N, N-1}|^2 = CN, \quad |X_{N, N+1}|^2 = C(N+1), \quad (4.13)$$

which is correct for the case treated before, that is, when $X = \sum x_j'$ or $X = \sum p_j'$. In such a case we have

$$\mathcal{F} = \frac{iC}{\hbar} \sum \pi \delta(\omega - \omega') \left\{ \left(\frac{\partial F_t}{\partial p_t} \right)_{n, l-1} x_{l-1, l} (N+1) - x_{l, n, n+1} \left(\frac{\partial F_t}{\partial p_t} \right)_{n+1, l} N \right. \\
+ \left. \left(\frac{\partial F_t}{\partial p_t} \right)_{n, l+1} x_{l+1, l} N - x_{l, n, n-1} \left(\frac{\partial F_t}{\partial p_t} \right)_{n-1, l} (N+1) \right\} \bar{\rho}_{l, n; N, N} \\
= \frac{iC}{\hbar} \sum \pi \delta(\omega - \omega') \left\{ \left(\frac{\partial F_t}{\partial p_t} \right)_{n, l} x_{l, l} - x_{l, n} \left(\frac{\partial F_t}{\partial p_t} \right)_{n, l} \left(\bar{N} + \frac{1}{2} \right) + \frac{1}{2} \left(\left(\frac{\partial F_t}{\partial p_t} \right)_{n, l-1} x_{l-1, l} \right. \right. \\
\left. \left. + x_{l, n, n+1} \left(\frac{\partial F_t}{\partial p_t} \right)_{n+1, l} - \left(\frac{\partial F_t}{\partial p_t} \right)_{n, l+1} x_{l+1, l} - x_{l, n, n-1} \left(\frac{\partial F_t}{\partial p_t} \right)_{n-1, l} \right) \right\} \bar{\rho}_{l, n; N, N}. \quad (4.14)$$

We take the trace as to the thermostat and write

$$\bar{f}_{l, n} = \sum_N \bar{\rho}_{l, n; N, N}, \quad \bar{N} = \sum_N N \bar{\rho}_{l, n; N, N} / \bar{f}_{l, n}, \quad (4.15)$$

Making use of the relation

$$ix_{n, n-1} = p_{n, n-1} / m\omega, \quad ix_{n, n+1} = -p_{n, n+1} / m\omega, \quad (4.16)$$

we get

$$\mathcal{F} = \frac{C}{m\omega\hbar} \sum \pi \delta(\omega - \omega') \left\{ \left(\frac{\partial^2 F_t}{\partial p_t^2} \right)_{n, l} \left(\bar{N} + \frac{1}{2} \right) \hbar\omega m - \frac{1}{2} \left(\frac{\partial F_t}{\partial p_t} p_t + p_t \frac{\partial F_t}{\partial p_t} \right)_{n, l} \right\} \bar{f}_{l, n}. \quad (4.17)$$

For the case $X = \sum x_j'$ or $X = \sum p_j' / m'\omega_j'$ we have $C = \hbar / 2m'\omega'$, and the coefficient in (4.14) gives ζ defined as (3.18), provided there are $D\omega'^2 d\omega' / (2\pi)^3$ oscillators within the frequency range from ω' to $\omega' + d\omega'$. In such a case we obtain (now $\bar{N}$ is the value for $\omega' = \omega$)

$$\frac{d}{dt} \text{Tr}(Ff) - \text{Tr}(F[H^0, f]) = \zeta \text{Tr} \left\{ \left(\frac{\partial^2 F}{\partial p^2} \left(\bar{N} + \frac{1}{2} \right) \hbar\omega m - \frac{1}{2} \left(\frac{\partial F}{\partial p} p + p \frac{\partial F}{\partial p} \right) \right) f \right\}. \quad (4.18)$$

The right hand side of the last equation can be modified using the identity

$$\text{Tr} \left(\frac{\partial A}{\partial p} f \right) = \frac{i}{\hbar} \text{Tr} \{ (Ax - xA) f \} = -\text{Tr} \left(A \frac{\partial f}{\partial p} \right). \quad (4.19)$$

Thus we get

$$\mathrm{Tr} \left(F \frac{\partial f}{\partial t} \right) - \mathrm{Tr} (F[H^0, f]) = \zeta \mathrm{Tr} \left\{ F \frac{\partial}{\partial p} \left(\left(\bar{N} + \frac{1}{2} \right) \hbar \omega m + \frac{1}{2} (pf + fp) \right) \right\} \quad (4.20)$$

which is quite analogous to (3.19). Further as the function F is arbitrary we almost recover (3.20) formally:

$$\frac{\partial f}{\partial t} - [H^0, f] = \zeta \frac{\partial}{\partial p} \left\{ \left(\bar{N} + \frac{1}{2} \right) \hbar \omega m + \frac{1}{2} (pf + fp) \right\}. \quad (4.21)$$

This equation goes over to (2.20) in classical limit because for $\hbar \rightarrow 0$,

$$\bar{N} + \frac{1}{2} \rightarrow kT/\hbar\omega, \quad [H^0, f] \rightarrow L^0 f.$$

§ 5. Friction Constant

Observation of (2.20) shows that the friction force acting on the particle is the Langevin force $-\zeta dx/dt$. Actually if one multiplies x and p to the both sides of (3.20) and integrates, one gets the average equations,

$$d\langle x \rangle/dt = \langle p \rangle/m, \quad (5.1)$$

$$d\langle p \rangle/dt = -m\omega^2 \langle x \rangle - \zeta d\langle x \rangle/dt. \quad (5.1')$$

Consequently one gets

$$d^2 \langle x \rangle/dt^2 + \zeta d\langle x \rangle/dt + \omega^2 \langle x \rangle = 0. \quad (5.2)$$

This is the well-known damping equation, or the "average" of the so-called Langevin equation.

We have pointed out that (5.2) can be derived directly from the Liouville equation⁶⁾. We shall show a simplified way of doing so. First we consider the classical case. We have

$$\langle x \rangle = \iint x \rho(x, p; x', p') d\tau d\tau'. \quad (5.3)$$

It is easy to see from (2.2) that

$$\frac{d\langle x \rangle}{dt} = \frac{\langle p \rangle}{m} + \lambda \iint \frac{\partial V}{\partial p} \rho d\tau d\tau'. \quad (5.4)$$

And further differentiation gives

$$\frac{d^2 \langle x \rangle}{dt^2} + \omega^2 \langle x \rangle = Y, \quad (5.5)$$

where Y stands for the friction term, given by

$$\begin{aligned} Y &= -\frac{\lambda}{m} \iint \frac{\partial V}{\partial x} \rho d\tau d\tau' + \lambda \frac{d}{dt} \iint \frac{\partial V}{\partial p} \rho d\tau d\tau' \\ &= -\frac{\lambda}{m} \iint \frac{\partial V_t}{\partial x_t} \rho_t d\tau_t d\tau'_t + \lambda \frac{d}{dt} \iint \frac{\partial V_t}{\partial p_t} \rho_t d\tau_t d\tau'_t. \end{aligned} \quad (5.6)$$

We insert the expression $\rho_t = \bar{\rho} + \lambda P(\bar{\rho}, t) + O(\lambda^2)$ into the right hand side of the last equation. As mentioned before we can drop the term proportional to the first power of λ , obtaining

$$Y = -\frac{\lambda^2}{m} \iint \frac{\partial V_t}{\partial x_t} P(\bar{\rho}, t) d\tau_t d\tau'_t + \lambda^2 \frac{d}{dt} \iint \frac{\partial V_t}{\partial p_t} P(\bar{\rho}, t) d\tau_t d\tau'_t. \quad (5.7)$$

For the special case $V=x \sum x_j'$ the above equation yields

$$Y = -\frac{\lambda^2}{m} \iint \sum_j x_{ij}' P(\bar{\rho}, t) d\tau_i d\tau_i' \\ = -\frac{\lambda^2}{m} \int_{-\infty}^t dt_1 \iint d\tau_i d\tau_i' \sum_j x_{ij}' \left\{ \left(\frac{\partial V_{t_1}}{\partial x_i} \frac{\partial \bar{\rho}}{\partial p_i} - \frac{\partial V_{t_1}}{\partial p_i} \frac{\partial \bar{\rho}}{\partial x_i} \right) + \dots \right\}. \quad (5.8)$$

We can perform the integration, as before, with respect to t_1 , which gives δ -function given by (3.11). We get finally

$$Y = -\zeta \frac{d\langle x \rangle}{dt} \quad (5.9)$$

with ζ given by (3.18).

Quantum mechanically

$$Y = -\frac{\lambda^2}{m} T_r \left(\frac{\partial V_t}{\partial x_t} P \right) + \lambda^2 \frac{d}{dt} T_r \left(\frac{\partial V_t}{\partial p_t} P \right) \quad (5.10)$$

corresponds to (5.7).

For the case $V=x \sum x_j'$, we get

$$Y = -\frac{\lambda^2}{m} T_r \left(\frac{i}{\hbar} \int_{-\infty}^t dt_1 x_{t_1} \{ \sum x_{t_1 i}' \sum x_{t_1 k}' - \sum x_{t_1 j}' \sum x_{t_1 k}' \} \bar{\rho} \right) \\ = -\frac{\lambda^2}{m} T_r \left\{ \left(\frac{i}{\hbar} \int_{-\infty}^t dt_1 \{ x_t \cos \omega(t_1-t) + (p_t/m\omega) \sin(t_1-t) \} \right. \right. \\ \left. \left. \times \sum \sum \left(\{ x_{tj}' \cos \omega_j'(t_1-t) + (p_{tj}/m'\omega_j') \sin \omega_j'(t_1-t) \} x_{tk}' - x_{tk}' \{ \dots \dots \} \right) \bar{\rho} \right) \right\}. \quad (5.11)$$

Using the relation $p_j' x_k' - x_k' p_j' = (\hbar/i) \delta_{jk}$ and (3.11), we get the same equation as (5.9) for the quantum mechanical case.

That analogous results are obtainable for other types of interaction is quite obvious. One gets, for instance, the Lozentz type of friction if the interaction is proportional to the momentum of the oscillator.

§ 6. Forced Oscillation and Energy Absorption

When an external force acts on the oscillator, it is clear that the only change in the treatment of the foregoing sections is to add a term to the hamiltonian H^0 of the oscillator. That is, we have

$$H^0(x, p) = \frac{p^2}{2m} + \frac{1}{2} m \omega^2 x^2 - x K(t). \quad (6.1)$$

This way of introducing the external force has the advantage that we can treat it however large it may be. Using the transformation of the type (2.4) or (4.2), the effect of the external force can be treated without relying on perturbation methods. For example the transformed x is now

$$x_t = x \cos \omega t + \frac{p}{m\omega} \sin \omega t + \frac{1}{m\omega} \int_0^t K(t') \sin \omega(t-t') dt'. \quad (6.2)$$

The equations (3.20) and (5.2) are changed respectively into

$$\frac{\partial f}{\partial t} + \frac{p}{m} \frac{\partial f}{\partial x} - \{ m \omega^2 x - K(t) \} \frac{\partial f}{\partial p} = \zeta \frac{\partial}{\partial p} \left(m k T \frac{\partial f}{\partial p} + p f \right), \quad (6.3)$$

$$d^2 \langle x \rangle / dt^2 + \zeta d \langle x \rangle / dt + \omega^2 \langle x \rangle = K(t) / m. \quad (6.4)$$

We shall calculate the energy absorbed by the oscillator. This is equal to the amount of work done by the oscillator against the external force. Thus the energy transferred from the external system to the oscillator is

$$\Delta H = - \left\langle \int K(t) dx \right\rangle = - \int K(t) \langle d\langle x \rangle / dt \rangle dt \quad (6.5)$$

where $\langle x \rangle$ is the solution of (6.4). If $K(-\infty) = K(\infty) = 0$ the increment in the total energy of the oscillator is

$$\Delta H = \frac{1}{m\omega_1} \int_{-\infty}^{\infty} dt e^{-\zeta t/2} \frac{dK}{dt} \int_{-\infty}^t dt' e^{\zeta t'/2} K(t') \sin \omega_1(t' - t) \quad (6.6)$$

with $\omega_1 = \sqrt{\omega^2 - \zeta^2/4}$.

When $K(t)$ is the force due to an incident particle, which interact with the oscillator by coulomb interaction, the above formula (6.6) gives the stopping power against the incident particle modified by the interaction with the surrounding. If the oscillator is isolated, that is if ζ vanishes, (6.6) reduces to the well-known formula:

$$\Delta H = \frac{1}{2m} \left| \int_{-\infty}^{\infty} e^{i\omega t} K(t) dt \right|^2.$$

§ 7. Discussion

We have seen that in a special case the problem we have considered so far is identical to that treated by Chandrasekhar using the theory of stochastic processes. Now, we note the fact that the solution of the Kramers equation (3.20) shows quite peculiar character as was pointed out by Wang and Unlenbeck⁷⁾. This behavior can be illustrated by the following example: Consider the energy of the oscillator given by

$$\langle E \rangle = \iint \left(\frac{p^2}{2m} + \frac{1}{2} m \omega^2 x^2 \right) f dx dp. \quad (7.1)$$

The rate of change of $\langle E \rangle$ is obtained from (3.20). That is

$$\frac{d}{dt} \langle E \rangle = 2\zeta \left(\frac{kT}{2} - \left\langle \frac{p^2}{2m} \right\rangle \right). \quad (7.2)$$

This means that the rate of change of the total energy of the oscillator is governed by its kinetic energy. This is very peculiar since, for instance, if the oscillator starts with a large displacement but zero momentum, having larger energy than kT , the total energy goes up first and then decreases. It approaches to kT of course, but every time the oscillator comes to largest displacement, the energy goes up a little. Thus the total energy of the oscillator shows oscillatory damping behavior, which is in sharp contrast to the following argument.

One considers the probability x_n , the diagonal element of the density matrix, that the oscillator is in the n -th quantum state. x_n will satisfy the Pauli equation of the form:

$$dx_n/dt = \frac{\gamma}{(1-e^{-\theta})} \{ n e^{-\theta} x_{n-1} - [n + (n+1)e^{-\theta}] x_n + (n+1)x_{n+1} \} \quad (7.3)$$

where γ is a constant proportional to the transition probability and $\theta = \hbar\omega/kT$. (7.3) can be obtained in many ways⁹⁾. But we shall only point out that (7.3) gives

$$d\bar{E}/dt = \gamma(\bar{E}_{eq} - \bar{E}), \quad \bar{E} = \sum x_n (n + \frac{1}{2}) \hbar\omega. \quad (7.4)$$

This is a smooth approach to equilibrium in contrast to (7.2).

Recently Zwanzig⁴⁾ derived a phase-space representation from (7.3). His result, including small off-diagonal elements, can be written as

$$\frac{\partial \bar{f}}{\partial t} + \frac{p}{m} \frac{\partial \bar{f}}{\partial x} - m\omega^2 x \frac{\partial \bar{f}}{\partial p} = \frac{r}{2} \left\{ \frac{\partial p \bar{f}}{\partial p} + mkT \frac{\partial^2 \bar{f}}{\partial p^2} + \frac{\partial x \bar{f}}{\partial x} + \frac{kT}{m\omega^2} \frac{\partial^2 \bar{f}}{\partial x^2} \right\} \quad (7.5)$$

in the classical limit. In (7.5) we write $\bar{f}$ instead of $\bar{f}$ because of the fact that this equation is concerned with the systematic part of the distribution function as will be seen below. It is easy to see that (7.5) shows smooth damping given by (5.4).

The very drastic difference between (3.20) and (7.3) (or (7.1) and (7.4)) can be explained in the following manner. As will be seen immediately below, (7.3), (7.4) and (7.5) are concerned with the systematic part, or the smooth part of the irreversible change. This situation will be made clear if one observes that the solution of (3.20) given by Wang and Unlekbeck⁷⁾ is of the form:

$$\langle E \rangle = kT + (\langle E \rangle_{t=0} - kT)e^{-\zeta t} + \zeta e^{-\zeta t} \times \left(\text{a function of } \frac{\sin \omega t}{\cos} \right) + O(\zeta^2). \quad (7.6)$$

One sees that $d\langle E \rangle/dt$ is oscillating as is given by (7.2), but also that $\Delta\langle E \rangle/\Delta t$ can be approximated by an equation of the form (7.4) with $r = \zeta$ if Δt is taken sufficiently large. We shall examine this point of view more systematically.

In classical mechanics it is more convenient to use, instead of x and p , the conjugate variables α and J , where α is the angle and J the action variable defined by

$$\alpha = -\text{tg}^{-1} p/xm\omega, \quad J = \frac{1}{\omega} \left(\frac{p^2}{2m} + \frac{1}{2} m\omega^2 x^2 \right). \quad (7.7)$$

Using these, for an assembly of harmonic oscillators,

$$L^0 = -\sum \omega_k \frac{\partial}{\partial \alpha_k}. \quad (7.7')$$

The transformation from ρ to ρ_t can be expressed, for the systematic part, as the transformation from $\bar{\rho}$ to the Fourier coefficients $\bar{\rho}_k$ defined by

$$\bar{\rho} = \sum \bar{\rho}_k(J, t) \exp i \sum n_k (\alpha_k - \omega_k t). \quad (7.8)$$

The master equation for the systematic part is ^{6), 8)}

$$\partial \bar{\rho}_n / \partial t = \lambda^2 \Omega \bar{\rho}_n - \lambda^2 M_n^2 \bar{\rho}_n, \quad (7.9)$$

where

$$\Omega = \pi \sum_{\mu} \left(\sum_k \mu_k \frac{\partial}{\partial J_k} \right) V_{-\mu} V_{\mu} \delta(\mu\omega) \left(\sum_k \mu_k \frac{\partial}{\partial J_k} \right), \quad (7.10)$$

$$M_n^2 = \pi \sum_{\mu} \left(\sum_k n_k \frac{\partial V_{-\mu}}{\partial J_k} \right) \left(\sum_k n_k \frac{\partial V_{\mu}}{\partial J_k} \right) \delta(\mu\omega) \quad (7.11)$$

in which we have used the expansion:

$$V = \sum V_{\mu}(J) \exp i \sum n_k \alpha_k. \quad (7.12)$$

We shall treat the case where the interaction is of the form

$$\begin{aligned} V &= \sum x_i x_j = \sum \sqrt{\frac{2J_i}{m_i \omega_i}} \cos \alpha_i \sqrt{\frac{2J_j}{m_j \omega_j}} \cos \alpha_j \\ &= \frac{1}{2} \sum \sqrt{\frac{J_i J_j}{m_i m_j \omega_i \omega_j}} (e^{\alpha_i + \alpha_j} + e^{\alpha_i - \alpha_j} + e^{-\alpha_i + \alpha_j} + e^{-\alpha_i - \alpha_j}). \end{aligned} \quad (7.13)$$

These four terms on the right hand side correspond to $V_{1,1}$, $V_{1,-1}$, $V_{-1,1}$ and $V_{-1,-1}$ respectively. When the thermostat is in equilibrium the distribution function $\bar{\rho}$ factorizes as

$$\bar{\rho} = \bar{f}(\alpha, J) \bar{\rho}_{th}(J') \quad (7.14)$$

where $\bar{\rho}_{th}$ is given by the Boltzmann law, i.e. $\bar{\rho}_{th} \sim \exp(-\sum \omega_j' J_j' / kT)$.

Integration with respect to the coordinates of the thermostat can be carried out, we shall denote the results by the bracket $\langle \rangle$. For instance we have

$$\langle \Omega \rho \rangle = 2\pi \frac{\partial}{\partial J} \left\{ \left\langle \sum_j |V_{1,-1(j)}|^2 \bar{\rho}_{th} \right\rangle \frac{\partial}{\partial J} + \left\langle \sum_j \left(\frac{\partial}{\partial J_j'} |V_{1,-1(j)}|^2 \right) \bar{\rho}_{th} \right\rangle \right\} \bar{f}, \quad (\omega_j' = \omega) \quad (7.15)$$

where

$$|V_{1,-1(j)}|^2 = \frac{1}{4} \frac{JJ_j'}{mm'\omega\omega'} \quad (7.16)$$

We get for $\omega' = \omega$

$$\begin{aligned} \langle |V_{1,-1(j)}|^2 \bar{\rho}_{th} \rangle &= \frac{J}{4mm'} \frac{kT}{\omega^3}, \\ \left\langle \frac{\partial |V_{1,-1(j)}|^2}{\partial J_j'} \bar{\rho}_{th} \right\rangle &= \frac{J}{4mm'\omega^2}, \end{aligned} \quad (7.17)$$

where $E = \omega J$ is the energy of the oscillator. Since we assume that there are $D\omega'^2 d\omega / (2\pi)^3$ oscillators in the thermostat within the frequency interval $\omega' < \omega_j' < \omega' + d\omega'$, using ζ defined by (3.18) we get

$$\lambda^2 \langle \Omega \bar{\rho} \rangle = \zeta \frac{\partial}{\partial E} E \left(kT \frac{\partial}{\partial E} + 1 \right) \bar{f}(\alpha, E). \quad (7.18)$$

Further we can rewrite M_n^2 as

$$M_n^2 = \frac{\pi}{8} \sum_j \left(\sum_i n_i \frac{1}{\sqrt{m_i m_j \omega_i \omega_j}} \sqrt{\frac{J_j}{J_i}} \right)^2, \quad (7.19)$$

so that

$$\langle \sum e^{t \sum n(\alpha - n t)} \lambda^2 M_n^2 \bar{\rho} \rangle = -\zeta \frac{kT}{4E} \frac{\partial^2}{\partial \alpha^2} \bar{f}, \quad (7.20)$$

Writing $E = r^2$ we get finally

$$\frac{\partial \bar{f}}{\partial t} + \omega \frac{\partial \bar{f}}{\partial \alpha} = \zeta \left\{ \frac{r}{2} \frac{\partial}{\partial r} + 1 + \frac{kT}{4} \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \alpha^2} \right) \right\} \bar{f}, \quad (7.21)$$

which is written in polar coordinates, the last bracket on the right being the Laplacian operator. If we go back to the coordinates $x\sqrt{m\omega/2}$ and $p/\sqrt{2m\omega}$, (7.21) yields (7.5), $r = \zeta$. This equation is valid even if ρ_n ($n \neq 0$) is not small. Thus the Zwanzig's equation has wider validity than he would have thought. But it is concerned with the systematic part only.

The quantum analogue of (7.7) is⁶⁾

$$\begin{aligned} \frac{d\bar{\rho}_{\alpha\alpha'}}{dt} &= \frac{\pi\lambda^2}{\hbar^2} \int d\alpha'' \left\{ -|V_{\alpha\alpha''}|^2 \delta\left(\frac{E_{\alpha''} - E_{\alpha}}{\hbar}\right) - |V_{\alpha'\alpha''}|^2 \delta\left(\frac{E_{\alpha''} - E_{\alpha'}}{\hbar}\right) \right\} \bar{\rho}_{\alpha\alpha''} \\ &\quad + 2 \frac{\pi\lambda^2}{\hbar^2} \int d\mu V_{\alpha, \alpha+\mu} \bar{\rho}_{\alpha+\mu, \alpha'+\mu} V_{\alpha'+\mu, \alpha} \delta\left(\frac{E_{\mu}}{\hbar}\right). \end{aligned} \quad (7.22)$$

The equation for the oscillator in the thermostat is obtained from (7.22):

$$\frac{1}{\zeta} \frac{\partial \bar{f}_{nn'}}{\partial t} = -\frac{1}{2} \{ (n+1)\bar{N} + n(\bar{N}+1) + (n'+1)\bar{N} + n'(\bar{N}+1) \} \bar{f}_{nn'} \\ + \sqrt{nn'} \bar{N} \bar{f}_{n-1, n'-1} + \sqrt{(n+1)(n'+1)} (\bar{N}+1) \bar{f}_{n+1, n'+1} \quad (7.23)$$

The corresponding density matrix in coordinate representation is

$$\bar{\rho}(q, q', t) = \sum \psi_n(q) \bar{f}_{nn'} \psi_n^*(q') \quad (7.24)$$

where ψ_n is the n -th eigen-function of the unperturbed oscillator. The equation of motion of the Wigner function

$$\bar{f}(x, p, t) = \frac{1}{\pi \hbar} \int_{-\infty}^{\infty} \exp(2ipy/\hbar) \bar{\rho}(x-y, x+y, t) dy \quad (7.25)$$

can be derived after some calculations which are quite similar to those of Zwanzig⁴⁾. Finally we get the equation of the form (7.5). The only difference is that kT is replaced by $(2\hbar\omega) \tanh(kT/2\hbar\omega)$.

§ 8. Concluding Remarks

The fundamental role of the oscillating part of the distribution function or of the density matrix is clarified. And a straight way of treating the problem of the Brownian motion has been given. In our formalism we split the distribution function into two parts: the systematic part and the oscillating part. The former obeys the master equation given by Philippot and Prigogine⁸⁾, and the equation derived by Zwanzig is equivalent to this. On including the oscillating part one gets another type of equation. As a special case one gets the Kramers equation. Without referring to the equilibrium state we get the friction constant and the correlation constant (or the diffusion constant in the momentum space). Thus our theory covers automatically the irreversible change and the equilibrium state.

The irreversible change towards equilibrium is attributed to the nature of the thermostat. To maintain the state of equilibrium the thermostat has to fulfill certain conditions such as the diagonal singularity condition of van Hove. The systematic part of the distribution function can be written as a product of the terms; one is for the oscillator and the other is for the thermostat. This does not imply that the distribution function factorizes. Actually the Liouville equation is not satisfied by a factorized distribution function. The factorization is true only for the systematic part.

It seems worth-while to stress that most of current theories in this field might lead to

incorrect results if they were used without caution. Because most of them are concerned only with the systematic part. Interference between the oscillating part and physical quantity to be considered may give rise to important contribution.

The system we have considered in this paper is of the same type to that of Callen and Welton⁹⁾ in treating the generalized Nyquist theorem. The author wishes to return to this subject in the near future.

The author wishes to express his thank to Prof. I. Prigogine of the Brussels University for illuminating discussions and communications. The resent study was partially financed by the Scientific Research Fund of the Ministry of Education.

Excess Noise in Narrow Germanium p - n Junctions

By Tatsuo YAJIMA*

*Technical Research Laboratory, Broadcasting Corporation
of Japan, Tokyo.*

and Leo ESAKI

Sony Corporation, Tokyo.

(Received June 3, 1958)

Excess noise has been studied on narrow alloyed p - n junctions fabricated on heavily doped p -type and n -type germanium with less than 200 Å junction width, which exhibit inverted rectification and negative resistance in the forward direction. Considerable $1/f$ noise has been observed in a forward range, the character of which is stable and surface insensitive. Moreover, the noise was found to be mainly associated with the excess forward current that is peculiar to narrow p - n junctions. Measurements were made also at low temperatures down to 77°K on both noise and static characteristics. The origins of the excess forward current and the associated excess noise were discussed in connection with the crystal imperfection.

§ 1. Introduction

In the recent experiment by one of the authors,^{1),2)} it was found that extremely narrow p - n junctions fabricated on heavily doped degenerate germanium exhibit much different current-voltage characteristics from those of the usual p - n junctions. The main features encountered are the inversion of rectification direction** and the existence of negative resistance in the forward direction. Both features are fairly well explained by considering Zener current; or internal field emission, across the energy gap at the junction. Moreover, various new effects will be expected associated with the properties of the material having high impurity concentrations. Therefore, the noise properties have been studied here as an inherent character of the device.

It has been well known that $1/f$ noise, or excess noise, appears commonly in almost all semiconductor devices and crystals accompanied with flowing current while it is absent in metals. In semiconductor crystals, however, an experimental tendency that the magnitude of $1/f$ noise becomes lower with the decrease in resistivity might be probably

accepted. Actually, it is usually difficult to observe $1/f$ noise in germanium single crystal filaments with the resistivity below about 1 ohm-cm. On the one hand, $1/f$ noise is believed to be predominantly a surface effect, because of its large dependence on surface conditions especially for reverse biased usual diode. Accordingly, most of the existing $1/f$ noise theories³⁾ include the surface as a part of the model, though exact picture has not yet been established.

Considering above facts, it was simply expected at first that the narrow p - n junction will have very low or no detectable $1/f$ noise, since the device is composed of metal-like semiconductor with extremely low resistivity of the order of 10^{-3} ohm-cm and its static characteristics are quite stable to surface conditions in the whole bias range. Practically we observed considerable $1/f$ noise in a certain bias range, and its properties were found to be somewhat different from those of the usual p - n junctions in several points. This is a subject of interest as a particular example of $1/f$ noise. It is the purpose of the present paper to describe the experimental results about this $1/f$ noise and to discuss the underlying physical processes.

§ 2. Samples and Noise Measurement

The samples are fabricated by alloying technique on heavily doped p -type and n -type

* Present address: Department of Physics, Faculty of Science, University of Tokyo, Tokyo.

** In this paper, we defined the *forward* direction of any p - n junction as the case where p -side is positively biased relative to n -side, regardless of the relative easiness of the current flow.

Table I.

Sample	Base Crystal				Alloying Dot
	conductivity type	doping agent	impurity content (cm ⁻³)	resistivity (ohm-cm)	component
5-12	<i>p</i>	pure Ga	1.6×10 ¹⁹	0.0021	0.5–1% P–In
IID-3	<i>n</i>	intermetallic In–P	1.2×10 ¹⁹	0.0015	0.5% Ga–In

germanium of $10^{18}\sim3\times10^{19}\text{ cm}^{-3}$ impurity concentration. The main features of the typical units used are listed in Table I.

Fig. 1 shows typical current-voltage characteristics of the narrow *p-n* junction. Large current in the reverse direction and current peak in the low voltage forward region can be attributed predominantly to Zener current corresponding to the electron transition between valence band and conduction band at the junction.^{1),2)} The current peak appears for the units having above about $2\times10^{18}\text{ cm}^{-3}$ impurity concentration, and the higher the concentration the higher the height of the peak. In the large forward voltage range, the observed characteristics were found to obey the usual diode current voltage relation

$$I=I_s[\exp(qV/kT)-1]$$

where q is the electronic charge, k is Boltzmann constant, T is the absolute temperature, and I_s is a constant. The whole static characteristics are quite stable both for ambient variation and light illumination unlike usual *p-n* junctions.

There still remains, however, an excess current component dominantly observable in the range from 0.2 volt to 0.4 volt at room temperature. Though the nature of this current component has not yet been completely explained, it was found to be related closely with the observed excess noise. This is the principal subject of this paper, and the more details will be described in the later sections.

Noise measurements were performed in the usual manner according to the circuit diagram as shown in Fig. 2. For the sample with

Fig. 1. Current—voltage characteristics of narrow *p-n* junction.

Fig. 2. Circuit diagram of noise measuring system.

large nonlinearity as in this case, it is necessary to determine the mean square short-circuit noise current $\overline{i_{ns}^2}$ and/or the mean square open-circuit noise voltage $\overline{v_{no}^2}$ correctly in order to know the intrinsic noise behavior of the units, because load resistance affects the observed noise characteristics considerably. ($\overline{i_{ns}^2}$ and $\overline{v_{no}^2}$ are simply related as $\overline{v_{no}^2} = r^2 \overline{i_{ns}^2}$, where r is the dynamic resistance of the sample). In the present case, they are determined through the simple circuit relations, using the measured values of the output noise voltage across a given load resistance and the sample dynamic resistance. Actual measurements were made approximately

under the open-circuit conditions due to the low sample resistance.

§ 3. Experimental Results

In the whole reverse region and in the forward region up to the current peak, we observed no detectable excess noise even for the open-circuit conditions. The situation is the same for negative resistance range. In this range, however, we were obliged to use very low load resistance below 10 ohm to set a stable bias, which results in great undesirable decrease of sensitivity of noise measurement. Although these results might be partly due to the low dynamic resistance of the sample, it seems to show that Zener current dominant in these range does not accompany particular excess noise. This seems to be in accordance with the previous results by other workers for less narrow *p-n* junctions.⁴⁾

On the other hand, considerably excess noise was observed beyond the current minimum in the forward direction. The frequency spectrum was found to show typical $1/f$ character and to be much higher above thermal and shot noise with white spectrum as indicated in Fig. 3. Also, this noise is fairly stable without pulsive character, and relatively surface insensitive. Even for the heavy ambient conditions, that is, dipping in water and some organic liquids such as benzene, carbontetrachloride, ethylalcohol, or, for the re-etching of the samples, no ap-

preciable changes of both noise and static characteristics were found. This is in contrast with the behavior usually associated with the $1/f$ noise.

The variation of the noise with the forward

Fig. 3. Noise frequency spectrum of narrow *p-n* junction.

voltage is shown in Fig. 4. The outstanding feature is that the mean square open circuit noise voltage $\overline{v_{no}^2}$ decreases rapidly with the bias voltage, while mean square short circuit noise current $\overline{i_{ns}^2}$ increases. From a simple equivalent circuit consideration, this can be interpreted as that the noise source is concentrated at the junction as a form of current generator which is nearly identical with i_{ns} , and that the decrease in $\overline{v_{no}^2}$ with the bias voltage is due to the change of barrier resistance of the junction. It is noted, however, that no such decrease in $\overline{v_{no}^2}$ has been found in the forward range of usual $p-n$ junctions. Series or bulk resistance seems to contribute to the excess noise in direct or indirect way in the latter case. In Fig. 5, $\overline{i_{ns}^2}$ of several units are plotted as a function of the forward current, simultaneously compared with that of the usual forward biased alloyed $p-n$ junctions. The latter represents an average characteristics of the excess noise of randomly selected 20 units, and the spread of the data among units is indicated by the hatched section. Two points should be noticed about the difference between narrow junctions and usual junctions. First, the noise level of narrow junction is much higher than that of the usual junction in the forward direction. Second, the current dependence of the noise for narrow $p-n$ junction deviate greatly from the normal square-law relation, i.e., $\overline{i_{ns}^2} \propto I^2$, for the $1/f$ noise, while it is nearly normal for usual junctions.

Above results can be interpreted phenomenologically in the following way. In the case of usual germanium $p-n$ junction diode, the observed forward current is known to consist almost only of the theoretical diode current, though modified by the series resistance, and hence the fact of normal current dependence for the excess noise may naturally be accepted. On the other hand, the forward current of narrow junction consists of three components, i.e., Zener current, diode current, and excess current, as described previously. In the voltage region of interest, the contribution of the theoretical Zener current will be negligible, and hence the last two components are sufficient to be considered. Since these two components can be thought to have different origins, it will be natural to consider

different $1/f$ noise sources for each component. Then, the spectral density of the observed noise current may be the sum of two independent mean square noise current generators accompanied by the diode current and the excess current, respectively, and is expressed by

$$\overline{i_{ns}^2} = K_1 \frac{I_a^2}{f} + K_2 \frac{I_{ex}^2}{f}$$

where I_a is the diode current, I_{ex} is the excess current and K_1, K_2 are the proportionality constants of different values. It is easily shown that in this case $\overline{i_{ns}^2}$ cannot be proportional to the square of the total current, $(I_a + I_{ex})^2$, unless I_a is always proportional to I_{ex} . This might explain the departure from the square-law current dependence. Furthermore, suppose that the excess current is much noisier than the diode current, i.e., $K_1 \ll K_2$, as is guessed from the results in Fig. 5. Then, the square-law relation between the noise and the excess current, instead of the total current, will be expected. By the method indicated in Fig. 1, we can always obtain the excess current as a monotonic increasing function of the voltage, except in the small region where normal diode current dominate extremely over the excess current and so the estimation of the latter becomes uncertain. Thus

Fig. 6. Mean square noise current as a function of excess forward current for narrow $p-n$ junctions.

Since we have not yet get a satisfactory explanation, only a brief qualitative discussion will be given below. The nature of the excess forward noise in usual p - n junction, which is the problem to be solved at the sametime, will not be concerned here.

First, it might be quite natural to suppose that the excess current is caused by some kinds of crystal imperfections, such as the dislocations or the impurity aggregate, due to the heavy doping. In fact, etch pit observation showed many characteristic pit clusters when the impurity amount becomes as high as 10^{20} cm^{-3} . However, the possibility of any current mechanism, arised from the thermal process governed by the activation energy or the potential barrier, may be excluded because of the relatively weak temperature dependence of the excess current. The current through local ohmic contacts is a possible cause with the desired temperature dependence. But it may be improbable because observed characteristics are non-ohmic, and noisy ohmic contact is unlikely. Another possibility is some non-ohmic leakage current through the imperfection at the junction, which can be large because of the small effective leakage path length due to narrow junction width. Surface leakage will also come to mind from the analogy of usual junction, but this must not be predominant, if present, since any heavy surface conditions do not greatly affect the characteristics as described previously. Now, one might question whether the excess current is peculiar to narrow p - n junctions or not. According to our measurements, we could not find such distinct excess current in the usual forward biased p - n junctions even at the liquid nitrogen temperature. This result seems to suggest that the excess forward current is governed not only by the degree of imperfection, even if it were so, but also by some another properties directly associated with the narrow junction width.

At this stage, an idea of another type of internal field emission will be proposed as a cause of the excess current. This can be considered to be present *in addition to the internal field emission*, previously introduced to explain the negative resistance, by the following reason. Since the internal field emission of the type described previously is the one produced by the direct interband

electronic transition at the junction, it must go to zero above the critical forward voltage where the bottom of the conduction band in the n -side coincide with the top of the valence band in the p -side.^{1),2)} This voltage is derived from the position of the Fermi level, and is estimated theoretically as ranging about 0.1~0.2 volt depending on the impurity concentration and temperature. Then, if any internal field emission mechanism is to be considered above this value, it must occur through the additional energy levels in the forbidden gap. Since there are many experimental evidences for the existence of such levels associated with the impurities and the dislocations, it will not be impossible that this new type of internal field emission causes the excess forward current with the temperature-insensitive character. Although we will not proceed further because of the lack of the necessary knowledge to treat the problem quantitatively, one following fact might be worth noticing. Namely, as is shown in Fig. 7, the excess current has a gradual but clear hump at low temperature centered in the range about 0.3~0.4 volt corresponding to about the half of the energy gap, and sometimes noise current also showed similar hump in the corresponding range. Since some impurity or dislocation levels are known to lie near the midgap in germanium, this would seem to suggest a correlation between these levels and the excess current.

If this is true, the associated excess noise will be understood naturally according to the following modulation mechanism. Apart from the explicit details, it is evident that the current produced by this cause will strongly depend on the situation of the imperfections and the associated field distributions near the junction. Since there would be the statistical fluctuations of the trapping and recombination processes through these levels such as suggested by Morrison⁷⁾ or of the impurity state itself, the resultant fluctuation of the population or the number of levels and of the neighbouring field distributions will strongly modulate the field emission current associated these levels. Further, if these modulation sources have $1/f$ type fluctuation, $1/f$ noise must arise.

Of course, above explanation is only a possibility, and it is hoped to seek more reason-

able point of view in future. There will be also a question whether the $1/f$ noise described here is actually different from the usual surface-sensitive $1/f$ noise in its intrinsic nature. Regarded from the general appearance of $1/f$ noise, it seems to be desirable to consider unified model for all the units exhibiting $1/f$ noise. However, it may be possible or even natural to suppose that the different physical causes of $1/f$ noise dominate for different types of device, as far as the underlying statistical elementary processes satisfy the mathematical requirement for the derivation of $1/f$ type spectrum.

In conclusion the authors wish to express their thanks to Miss Y. Kurose for her assistance in the experiment and the calculations.

A Theory of Impurity Conduction. II

By Tadao KASUYA and Sigenao KOIDE

Physical Institute, Nagoya University

(Received June 25, 1958)

The impurity band conduction was treated where the resonance energy (or the translational energy) is much smaller than the fluctuation of local potential energy. By the interaction with phonon, electron can hop from one localized state to another, exchanging the difference of the local potential energies for a phonon. The agreement between theoretical and experimental results is fairly satisfactory.

§ 1. Introduction

In the previous paper¹⁾ (hereafter referred to [1]), one of us discussed impurity conduction of semiconductor, and classified it as follows.

(1) High impurity concentration: In this range, impurity levels are merged into conduction band, and we can treat the problem as a single band conduction. Then, impurity atoms play a role of scatterers.

(2) Low impurity concentration: When the concentration of impurity atoms becomes smaller, impurity levels are separated from the conduction band. Our problem is how to treat

the transport phenomena in this impurity level. In the range (2), we treat the case that the energy width of impurity band is determined mainly by the resonance energy between atomic wave functions localized in different impurity atoms.

We treated these cases in [1], and here we treat the third case, that is:

(3) Very low impurity concentration: When the concentration of impurity atoms becomes very small, the fluctuation of local potential energy becomes much larger than the resonance energy which corresponds to the translational energy. Thus the localized state be-

longing to a particular impurity atom becomes stable, and transport phenomena hardly occur if we consider only the freedom of electron system. In this situation, the interaction of electron with phonon system becomes important because electron is possible to walk about the whole crystal by hopping from one localized state to the other, exchanging the difference of the local potential energy for phonon system.

To perform the calculation practically in Ge and Si, we must consider the complex effects of band structures in both n- and p-type. In n-type Ge and Si, the conduction band has many valley structure and as many degenerate states as a number of valleys exist. In p-type, the valence band is constructed by three degenerated bands. By the effects of spin-orbital interaction, these degeneracy are released partly and the band structure becomes such that: two bands with different effective masses are degenerated at $\mathbf{k}=0$, and the other one band has lower energy than these two bands at $\mathbf{k}=0$ in order of spin-orbital interaction energy. Localized states composed by these bands are fairly complicated and considered in §2. In §3, we treat the effect of electron-phonon interaction. In §4 the mechanism of conduction is discussed, and in §5 the comparison with experimental results is done.

§2. Localized State of Ge and Si

At first, we treat electronic states trapped by a particular impurity atom when the effects of the other impurity atoms are negligibly small.

We begin with n-type. When there is no impurity atom, wave functions of electron can be expressed by Bloch function

$$\psi_{\mathbf{k}}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{\mathbf{k}}(\mathbf{r}) \quad (1)$$

We can rewrite it as a following form

$$\psi_{\mathbf{k}_i}(\mathbf{r}) = e^{i\mathbf{k}_i\cdot\mathbf{r}} u_{\mathbf{k}_i}(\mathbf{r}) \quad (2)$$

$$u_{\mathbf{k}_i}(\mathbf{r}) = e^{i\mathbf{K}_i\cdot\mathbf{r}} u_{\mathbf{K}_i+\mathbf{k}_i}(\mathbf{r}) \quad (3)$$

where $\mathbf{K}_i$ is the wave vector of the state corresponding to the bottom of i -th valley, and $\mathbf{k}_i$ means the wave vector measured from the bottom of i -th valley.

The potential of impurity atom may be written in a form

$$V(\mathbf{r}) = -\frac{e^2}{\epsilon_0 r} \quad (4)$$

where $\mathbf{r}$ is measured from the center of the impurity atom, and ϵ_0 is dielectric constant. Then, if $\mathbf{k}_i$ dependence of $U_{\mathbf{k}_i+\mathbf{k}_i}$ is negligible, 1s state composed by the i -th valley may be approximated by the following form as shown by Kittel-Mitchell²⁾.

$$\begin{aligned} \varphi_{1s,i}(\mathbf{r}) &= \left(\frac{ab^2}{\pi r_0^3} \right)^{1/2} \exp \left[-\{a^2 x^2 + b^2 (y^2 + z^2)\}^{1/2} / r_0 \right] \\ &\times e^{i\mathbf{K}_i\cdot\mathbf{r}} u_{\mathbf{k}_i}(\mathbf{r}), \end{aligned} \quad (5)$$

where

$$r_0 = \frac{\epsilon_0 \hbar^2}{m e^2}, \quad (6)$$

and parameters are given in Ge and Si as follows

	Ge	Si
$\epsilon_0 =$	16	12
$a^2 =$	0.135	0.216
$b^2 =$	0.017	0.073

In rigorous sense, however, $\varphi_{1s,i}$ is not orthogonal to $\varphi_{1s,j}$ when i and j represent different valleys. In Ge and Si, however, as shown by Kittel-Mitchell, $\mathbf{K}_{ij} r_0 / a$ or b (where $\mathbf{K}_{ij} = \mathbf{K}_i - \mathbf{K}_j$) is sufficiently larger than 1, and we can consider in fairly good approximation that $\{\varphi_{1s,i}\}$ are nearly orthogonalized each other. On the other hand, $V_{ij} = \langle \varphi_{1s,i} | V | \varphi_{1s,j} \rangle$ remains in lower order than $\langle \varphi_{1s,i} | \varphi_{1s,j} \rangle$ with respect to $a / \mathbf{K}_{ij} r_0$ and we can not neglect this effect. From this effect, wave functions of 1s states may be approximated by the linear combinations of $\varphi_{1s,i}$ with same weight, that is,

$$\psi_{1s,i} = \frac{1}{\sqrt{n_0}} \sum_j C_j' \varphi_{1s,j}, \quad (8)$$

where $|C_j'|$ is constant, and n_0 is the number of valleys. The degeneracy of energy spectrum is also released. Energy splitting by this effect may be of the order of V_{ij} . To estimate the order of V_{ij} , we use the isotropic effective mass $m^* = (m_l m_t^2)^{1/3}$, where m_l and m_t are respectively longitudinal and transversal effective masses, and further assume that $\int_{\Omega_0} u_{\mathbf{K}_i}^*(\mathbf{r}) u_{\mathbf{K}_j}(\mathbf{r}) d\mathbf{r} = 1$. Then a and b are replaced by m^*/m and V_{ij} becomes

$$V_{ij} = -\frac{e^2}{\epsilon_0 r_0^* [1 + (\mathbf{K}_{ij} r_0^* / 2)^2]}, \quad (9)$$

where

$$r_0^* = \frac{m}{m^*} r_0. \quad (10)$$

For example, in Ge, if we take K_{ij} as the principal wave vector in the direction of $[1, 1, 1]$, V_{ij} becomes 0.2κ , and nearly the same order in Si, too. Fluctuations of local potential energy are more than 10κ in Fritzsche's samples⁹⁾ as shown in Table I, and thus we may neglect, in the following consideration, the effect of energy splitting of $1s$ states compared with the local fluctuation energy.

When the overlapping of $1s$ wave functions locating at the nearest neighbour impurity atoms becomes large, the wave function which makes the overlapping most effective becomes stable. In this case, Eq. (8) are not applicable.

In p-type Ge and Si, it is very difficult to calculate $1s$ state theoretically due to the degenerated band structure. Experimentary, however, ionization energies of electron in impurity level were observed, that is, 0.01 e.v. in p-type Ge and 0.05 e.v. in p-type Si. If we assume that in this case, too, a hydrogen like wave function is applicable and effective mass is considered as isotropic, m^*/m becomes 0.19 in Ge and 0.53 in Si. In § 5, we compare these values with that obtained as to satisfy the experimental results of mobility of p-type Ge and Si.

§ 3. Electron-Phonon Interaction

In the preceding section, we considered $1s$ states where only one impurity atom exists. When there exist more than one impurity atoms, mixing of $1s$ wave functions localizing at different impurity atoms occurs even if we do not consider the effect of electron-phonon

interaction, because these $1s$ wave functions are not orthogonalized. At first, we consider this mixing effect by choosing only two nearest neighbours impurity atoms, because in this paper we treat only the case that in average the difference of local potential energy at two impurity atoms is much larger than the resonance energy between $1s$ wave functions localized in these impurity atoms induced by non-orthogonality of these wave functions, and thus the ratio of the mixing is small and we can regard each electron to be trapped approximately in each impurity atom.

When there are two impurity atoms locating in position $\mathbf{R}_1$ and $\mathbf{R}_2$, the real wave function Ψ may be approximated by the linear combination of $1s$ wave functions ϕ_1 and ϕ_2 localized respectively in impurity atoms of position $\mathbf{R}_1$ and $\mathbf{R}_2$

$$\Psi = c_1\phi_1 + c_2\phi_2, \quad (11)$$

Hamiltonian of this system is written as

$$H = H_0 + V_1(|\mathbf{r} - \mathbf{R}_1|) + V_2(|\mathbf{r} - \mathbf{R}_2|) + v(r), \quad (12)$$

where H_0 is the Hamiltonian with periodic potential, V_1 and V_2 mean respectively the potentials of impurity atoms at positions $\mathbf{R}_1$ and $\mathbf{R}_2$, and $v(r)$ is potential energy changing very slowly in space mainly induced by minority impurity atoms. c_1 and c_2 are determined by variation principle, and we obtain the wave functions of ground state Ψ_1 and excited state Ψ_2 as

$$\Psi_1 = x_1\phi_1 + \phi_2 / (1 + 2x_1J + x_1^2)^{1/2} \quad (13)$$

$$\Psi_2 = x_2\phi_1 + \phi_2 / (1 + 2x_2J + x_2^2)^{1/2} \quad (14)$$

where

$$x_{1,2} = [v_1 - v_2 \pm \{(v_1 - v_2)^2 + 4(v_1 - v_2)JL + 4L^2\}^{1/2}] / 2L, \quad (15)$$

$$L = \langle \phi_1 | V_2 + v | \phi_2 \rangle - \langle \phi_1 | V_2 + v | \phi_1 \rangle J, \quad (16)$$

$$J = \langle \phi_1 | \phi_2 \rangle, \quad (17)$$

$$v_i = \langle \phi_i | v | \phi_i \rangle, \quad i = 1, 2, \quad (18)$$

and we took that $v_1 < v_2$.

When a perturbation H' is added, the transition matrix element $\langle \Psi_1 | H' | \Psi_2 \rangle$ is given from Eqs. (13) and (14) by

$$\langle \Psi_1 | H' | \Psi_2 \rangle = \frac{x_1x_2H'_{11} + H'_{22} + (x_1 + x_2)H'_{12}}{(1 + 2Jx_1 + x_1^2)^{1/2}(1 + 2Jx_2 + x_2^2)^{1/2}}, \quad (19)$$

where

$$H'_i = \langle \phi_i | H' | \phi_i \rangle, \quad i = 1, 2, \quad (20)$$

$$H_{12}' = \langle \psi_1 | H' | \psi_2 \rangle, \quad (21)$$

and further using the assumption that $v_2 > v_1$, $|x_1| \gg 1 \gg |x_2|$ which corresponds to the assumption that the local fluctuation energy $|v_2 - v_1|$ is much larger than the resonance energy L , Eq. (19) is approximated by

$$\begin{aligned} \langle \Psi_1 | H' | \Psi_2 \rangle &= \frac{1}{2} (H_1' + H_2') J - H_{12}' \\ &+ \frac{H_2' - H_1'}{v_2 - v_1} \left\{ \langle \psi_1 | V_2 | \psi_2 \rangle - \langle \psi_1 | V_2 | \psi_1 \rangle J + \langle \psi_1 | v | \psi_2 \rangle - \frac{v_1 + v_2}{2} J \right\}. \end{aligned} \quad (22)$$

As to replace H' for usual electron-phonon interaction, however, it remains a complicated problem. In usual electron-phonon interaction, the motion of electron is more rapid than that of ion, and thus we can use adiabatic approximation for the motion of electron. In our hopping model of impurity conduction, however, the time of hopping becomes rather larger than the periodic time of the motion of lattice, and the hopping of electron from one localized state to the other accompanies the motion of the deformation of lattice. This effect is interesting problem in itself and may be important also in other phenomena. In this paper, however, we adopt the zeroth approximation to neglect the effect of deformation of lattice, and discussion about this problem should be given in an other paper.

As to H' , we use here the form of deformation potential proposed by Bardeen-Shockley⁴⁾.

$$H' \equiv H_{ep} = \sum_{\mathbf{q}} D q e^{i\mathbf{q}\cdot\mathbf{r}} \xi_{\mathbf{q}}, \quad (23)$$

where D is the coupling constant of electron-phonon interaction and $\xi_{\mathbf{q}}$ means the coordinate of acoustical phonon of longitudinal mode with wave vector $\mathbf{q}$, and the matrix element of $\xi_{\mathbf{q}}$ is

$$\langle N_{\mathbf{q}} | \xi_{\mathbf{q}}^* | N_{\mathbf{q}} - 1 \rangle = \langle N_{\mathbf{q}} - 1 | \xi_{\mathbf{q}} | N_{\mathbf{q}} \rangle = \left(\frac{\hbar N_{\mathbf{q}}}{2M\omega_{\mathbf{q}}N} \right)^{1/2}, \quad (24)$$

where M is the mass of each lattice point, N is the number density of lattice point, and $\omega_{\mathbf{q}}$ is the angular velocity of phonon with wave vector $\mathbf{q}$. Optical mode is not important in region of impurity conduction. In Eq. (22), the third term may, in general, be considered as smaller than the first term, and the second term is also smaller than the first term due to the oscillation term $e^{i\mathbf{q}\cdot\mathbf{r}}$ of Eq. (23). From the above consideration, we adopt only the first term hereafter, and the square of the matrix element becomes

$$|\langle \Psi_1 | H_{ep} | \Psi_2 \rangle|^2 \equiv |W_{12}(A)|^2 = \frac{1}{4} \frac{D^2 \Delta_{12}}{NM S^2} J_{12}^2 (1 - \cos \mathbf{q} \mathbf{R}_{12}) \quad (25)$$

where Δ_{12} is the energy difference between two states, Ψ_1 and Ψ_2 , and nearly equals to $|v_2 - v_1|$, S is the velocity of the longitudinal phonon and the wave vector $\mathbf{q}$ is determined by the condition of energy balance

$$\hbar \mathbf{q} \mathbf{u} = \Delta_{12} \quad (26)$$

In samples we refer, Δ_{12} is nearly the order of 10 eV and then $\mathbf{q} \mathbf{R}_{12}$ becomes the order of 10 and thus the term $\cos \mathbf{q} \mathbf{R}_{12}$ cancels out each other in average. J_{12} is the overlapping integral, $|\langle \psi_1 | \psi_2 \rangle|$, and written in p-type Ge and Si as

$$J_{12} = \left| \exp \left(-\frac{R_{12}}{r_0^*} \right) \left\{ 1 + \frac{R_{12}}{r_0^*} + \frac{1}{3} \left(\frac{R_{12}}{r_0^*} \right)^2 \right\} \right|, \quad (27)$$

when the ground state wavefunction of p-type impurity level is represented by the hydrogen like 1s function with isotropic effective mass m^* . In n-type Ge and Si, if we write the ground

state wave function by the type of Eq. (8), we obtain the following form using the approximation that wave functions of different valleys are nearly orthogonal, and the energy splitting of states $\{\psi_{1s,i}\}$ is negligible,

$$J_{12}^2 = \frac{1}{n_0^2} \sum_i \left| \sum_i c_i^l c_i^{l'} \langle \varphi_{1s,i}(R_1) | \varphi_{1s,i}(R_2) \rangle \right|^2 = \frac{1}{n_0^2} \sum_i \left| \langle \varphi_{1s,i}(R_1) | \varphi_{1s,i}(R_2) \rangle \right|^2, \quad (28)$$

by the relation between the coefficients c_i^l

$$\sum_i c_i^l c_j^l = n_0 \delta_{ij}. \quad (29)$$

Eq. (28) is also applicable when 1s state is not written by Eq. (8) but single valley wave function (5). Using Eq. (5)

$$J_{12}^2 = \frac{1}{n_0^2} \sum_i \left| \exp \left(-\frac{R_{12}^{i*}}{r_0} \right) \left\{ 1 + \frac{R_{12}^{i*}}{r_0} + \frac{1}{3} \left(\frac{R_{12}^{i*}}{r_0} \right)^2 \right\} \right|^2, \quad (30)$$

where

$$R_{12}^{i*} = [(aR_{12,x}^i)^2 + (bR_{12,y}^i)^2 + (bR_{12,z}^i)^2]^{1/2}. \quad (31)$$

and $R_{12,x}^i$ etc. are measured by the coordinate of i -th valley. Or, we may replace summation by valley, $\sum_i$, in Eq. (30) by integration by the direction of $\mathbf{R}_{12}$. Then J_{12} becomes

$$J_{12}^2 = \int_0^1 dx \exp \{ -2bd(1+(t^2-1)x^2) \} \left[1 + bd(1+(t^2-1)x^2)^{1/2} + \frac{b^2d^2}{3}(1+(t^2-1)x^2) \right]^2, \quad (32)$$

where $d = R_{12}/r_0$, and $t = a/b$, and when d is fairly larger than unity, J_{12} is approximated by

$$J_{12}^2 = \frac{\sqrt{\pi}}{2} \sqrt{\frac{br_0}{(a^2-b^2)R_{12}}} \left| \exp \left(-\frac{bR_{12}}{r_0} \right) \left\{ 1 + \frac{bR_{12}}{r_0} + \frac{1}{3} \left(\frac{bR_{12}}{r_0} \right)^2 \right\} \right|^2. \quad (33)$$

We neglected here the second order effects (see Appendix I).

§ 4. Mechanisms of Conduction

In this section, we consider the mechanisms of conduction. Our model adopted in this section is such that: Fluctuation of local potential energy is much larger than resonance energy and localized state of electron trapped by a particular impurity atom is nearly stable if we do not consider electron-phonon interaction. By electron-phonon interaction, electron can hop from one localized state to the other emitting or absorbing a phonon. We consider that initially there is no external electric field and then the system is in thermal equilibrium. Then the distribution function f_n , which means the probability to find a electron in the localized state belonging to the impurity atom locating at R_n , is represented approximately by Fermi distribution function $f(\epsilon_n)$,

$$f(\epsilon_n) = [\exp \epsilon_n + 1]^{-1}, \quad \epsilon_n = \frac{E_n - \zeta}{kT}, \quad (34)$$

where E_n is the energy of the state ψ_n and we may approximate it by the local potential energy v_n as in Eq. (18). ζ is the chemical potential and given by

$$\sum_n f(\epsilon_n) = N_{\text{maj}} - N_{\text{min}} \quad (34)$$

When external electric field F is applied on the system, the probability of hopping to the direction of electric field increases, and the electric current begins to flow in the direction of electric field. In steady state, the distribution function f_n should satisfy the following condition

$$\left(\frac{\partial f_n}{\partial t}\right)_{\text{coll}} = \frac{2\pi}{\hbar} \sum_n \sum_q |W_{nm}(q)|^2 \left\{ f_m(1-f_n) \left[\frac{N(q)+1}{N(q)} \right] - f_n(1-f_m) \left[\frac{N(q)}{N(q)+1} \right] \right\} \times \delta(E_n - E_m - eFX_{nm} \pm \hbar\omega_q) = 0 \quad (35)$$

where $|W_{nm}(q)|^2$ is the constant of transition probability and given by Eq. (25). $N(q)$ is the distribution function of phonon with wave vector q given by Eq. (26) and upper or lower part is taken corresponding to $E_n \geq E_m$. Here we assume that the phonon system is always in thermal equilibrium, and thus $N(q)$ is given by

$$N(q) = \left[\exp \frac{\hbar\omega_q}{\kappa T} - 1 \right]^{-1}. \quad (36)$$

When the distribution function in steady state is obtained by Eq. (35), the electric current J_x in steady state is given by

$$J_x = e \frac{2\pi}{\hbar} \sum_{(n,m)} \sum_q |W_{nm}(q)|^2 X_{nm} \left\{ f_n(1-f_m) \left[\frac{N(q)}{N(q)+1} \right] - f_m(1-f_n) \left[\frac{N(q)+1}{N(q)} \right] \right\} \times \delta(E_m - E_n + eFX_{nm} \pm \hbar\omega_q). \quad (38)$$

It is very difficult to solve the Eq. (35) rigorously due to the random distribution of impurity atom. For this reason, we use in following some simplified model and calculate it in some extreme cases.

At first, we consider the case that f_n is replaced approximately by $f(\epsilon_n)$. To examine this assumption, we replace f_n in Eq. (35) by $f(\epsilon_n)$. Then, using the linear theory with respect to external field,

$$\begin{aligned} \left(\frac{\partial f_n}{\partial t}\right)_{\text{coll}} &= \frac{2\pi}{\hbar} \sum_n \sum_q |W_{nm}(q)|^2 f(\epsilon_n) f(\epsilon_m) N(q) \frac{eFX_{nm}}{\kappa T} \left[\frac{e^{\epsilon_m}}{e^{\epsilon_n}} \right] \delta(E_n - E_m \pm \hbar\omega_q) \\ &= 6\pi \frac{eFN}{\hbar\kappa T(\kappa\Theta)^3} \sum_n \frac{|W_{nm}(q)|^2 \Delta_{nm}^2 X_{nm}}{(e^{\epsilon_n}+1)(e^{-\epsilon_m}+1)|e^{\epsilon_m-\epsilon_n}-1|}. \end{aligned} \quad (39)$$

As is easily seen from Eq. (39), if the distribution of impurity atoms and the local potential energy are symmetric with respect to the point R_n , $(\partial f/\partial t)_{\text{coll}}$ becomes zero, namely, $f(\epsilon_n)$ represents the distribution function of steady state. In case (I) of Fig. 1, that is, when N_{maj} is not so larger than N_{min} , the situation of the surrounding of any point R_n may be regarded as nearly at random, and in average the distribution of impurity atoms and the local potential may be considered as

symmetrical distribution in not a so bad approximation. Therefore, we may replace f_n by $f(\epsilon_n)$ in case (I).

In case (II) of Fig. 1, that is, when N_{maj} is much larger than N_{min} , the approximation to replace f_n by $f(\epsilon_n)$ becomes not so good. In this case, it may be more convenient to consider the impurity atoms by deviding into the molecules as is represented by dotted line in Fig. 1. Each molecule has one minority impurity atom, in the center, and in average contains one hole which suffers attractive Coulomb force to the direction of the minority impurity atom at center (hereafter, we consider the case of n-type. In p-type, too, the situation is just same as that of n-type when we exchange the role of electron for hole.). At first, let us look at the points R_1 and R_2 near by the centered minority impurity atom as in Fig. 1. In the point R_1 , we may say that $E_1 \geq E_n$ corresponding to $X_1 \leq X_n$ comparing to the point R_n near by R_1 . If the space distribution of majority impurity atoms

Fig. 1.

- ⊖ means the position of minority impurity atom
- ⊕ means the position of majority impurity atom
- means the direction of current flow

is considered as nearly symmetrical with respect to R_1 , $(\partial f_{R_1}/\partial t)_{\text{coll}}$ becomes negative, that is, the probability to find a electron in the localized state belonging to the impurity atom at R_1 decreases. In the position R_2 , the situation is reversible and $(\partial f_{R_2}/\partial t)_{\text{coll}}$ becomes positive. The above situation becomes weak at point R_3 near by the surface of the molecule, and here the distribution function f_{R_3} may be replaced by $f(\epsilon_n)$ in a fairly good approximation. Thus, we may say that each molecule suffers polarization by the existence of the external field in near neighbours of the minority impurity atom, and the electrical current occurs by transition of hole from one molecule to the other. Therefore we calculate the electrical conductivity in the case (II) by using a following model: The electrical current in steady state is determined mainly by the transition of hole from a state localized at a majority impurity atom locating near by surface of a certain molecule to that of another molecule, and the distribution function f_{R_n} near neighbour of the surface of the molecule is replaced by $f(\epsilon_n)$.

In the following, we calculate the electrical conductivity in case (I) and (II) more qualitatively.

Case (I). N_{maj} is not so larger than N_{min} , and f_n is replaced by $f(\epsilon_n)$.

Eq. (38) becomes

$$J_x = e^2 F \frac{6\pi N}{\hbar(\kappa\Theta)^3 \kappa T} \times \sum_{(nm)} \sum \frac{|W_{nm}(q)|^2 \Delta_{nm}^2 X_{nm}^2}{(e^{\epsilon_n} + 1)(1 + e^{-\epsilon_m})|e^{\epsilon_m - \epsilon_n} - 1|}. \quad (40)$$

To calculate Eq. (40) more qualitatively, we use further the following approximation. As is seen from Eq. (25), $W_{nm}(q)$ decreases rapidly when R_{nm} becomes larger, because it contains the overlapping integral J_{nm} . Therefore, it is sufficient to consider only the terms with small value of R_{nm} in the summation with respect to R_{nm} . However, it may be given a non sense result to consider only nearest neighbour impurity atom, because this current gives

Fig. 2.

= means the polarization current

merely a polarization current as is seen from Fig. 2, and should vanish in the true distribution function of steady state. Therefore we must consider at least until next nearest neighbours impurity atom in the summation with respect to R_{nm} . Further, we define d as a mean distance between these next nearest neighbours impurity atoms, and replace R_{nm} by d . Here, we determine the value of d by

$$d = \left(\frac{2\pi}{3} N_{\text{maj}} \right)^{-1/2}, \quad (41)$$

which corresponds to the condition that when each impurity atom has average volume N_{maj}^{-1} , we can find two other impurity atoms when we draw a sphere of radius d with the center on the given impurity atom (see Appendix II). Then we can rewrite Eq. (40) as

$$J_x = e^2 F \frac{2\pi N d^2}{\hbar(\kappa\Theta)^3 \kappa T} \int_{-\infty}^{\infty} F(E) dE \times \int_{-\infty}^{\infty} G(E, \Delta) d\Delta \frac{|W_d(\Delta)|^2 \Delta^2}{(e^{\epsilon} + 1)(1 + e^{-\epsilon - x})|e^x - 1|}, \quad (42)$$

where

$$x = \Delta / \kappa T, \quad (43)$$

and $F(E)dE$ is the number of majority impurity atom with local potential energy of value between E and $E+dE$, and $G(E, \Delta)d\Delta$ means the probability that when the impurity atom with the potential energy E is given, the other impurity atom with distance d from the given impurity atom and the potential energy of value between $E+\Delta$ and $E+\Delta+d\Delta$ is observed. These quantities are normalized such as

$$\int_{-\infty}^{\infty} F(E) dE = N_{\text{maj}} \quad (44)$$

$$\int_{-\infty}^{\infty} G(E, \Delta) d\Delta = 1 \quad (45)$$

Next, we calculate $F(E)$ and $G(E, \Delta)$, using the following simplified model.

[Calculation of $F(E)$]. Now we consider a sphere of volume Ω_0 with center on a given minority impurity atom. Average volume of Ω_0 is N_{min}^{-1} and it is assumed that in each sphere, there is one hole in average and the potential energy within this sphere is determined by Coulomb field of the minority impurity atom at the center and effects from the other spheres are canceled out in average because they are neutral in average. As the distribution of majority impurity atoms is as-

sumed as uniform, the probability to find majority impurity atom in the distance between r and $r+dr$ from the centered minority impurity atom is proportional to $r^2 dr$. As Coulomb field is proportional to $-1/r$, $F(E)dE$ is proportional to dE/E^4 . On the other hand, from the normalization condition, the relation

$$\int_{-\infty}^{-5} F(E)dE = N_{\min} \quad (46)$$

exists, and thus $F(E)$ becomes

$$F(E) = N_{\min} \frac{3\zeta^3}{E^3} \quad (47)$$

where ζ is determined by

$$\zeta = \frac{e^2}{\epsilon_0} \left(\frac{4\pi}{3} N_{\text{maj}} \right)^{1/3} \equiv \frac{e^2}{\epsilon_0 d_{\text{maj}}} \quad (48)$$

The upper limit E_0 of impurity band is determined by the normalization condition (44) and E_0 becomes

$$E_0 = \frac{e^2}{\epsilon_0} \left(\frac{4\pi}{3} N_{\min} \right)^{1/3} \equiv \frac{e^2}{\epsilon_0 d_{\min}} \quad (49)$$

In the temperature range where impurity conduction is important, ζ is much larger than κT for almost samples we consider. In this case, we can write

$$F(E) \doteq F(\zeta) = \frac{3N_{\min}}{\zeta} \quad (50)$$

[Calculation of $G(E, d)$]. Calculation of $G(E, d)$ is more difficult than that of $F(E)$, because in former calculation inter molecular transition is important. In a rough approximation, E may be replaced by ζ as mentioned above, and when d becomes negative $G(E, d)$ may be small and thus replaced zero in this range. When d is positive, however, we may say approximately that $G(\zeta, d)$ does not depend on d , corresponding to the assumption to replace f_n by $f(\epsilon_n)$. Thus from the normalization condition (45) we can write that

$$G(\zeta, d) = (\zeta - E_0)^{-1} \quad \text{when } 0 < d < \zeta - E_0 \\ = 0 \quad \text{otherwise} \quad (51)$$

Using Eqs. (50) and (51), we can obtain J_x as

$$J_x = e^2 F \frac{3\pi}{2} N_{\min} \frac{d^2 D^2 \kappa \Theta}{\hbar M u^2 \zeta (\zeta - E_0)} \\ \times \left(\frac{T}{\Theta} \right)^4 J_a^2 \phi_4 \left(\frac{\zeta - E_0}{\kappa T} \right), \quad (52)$$

where

$$\phi_n(x) = \int_0^{\infty} \frac{y^n dy}{(e^y - 1)(1 - e^{-y})}. \quad (53)$$

As a condition of applicability of Eq. (52), we may say roughly such that; electron can transfer from one atomic state with energy ζ localizing at a majority impurity atom belonging to a certain sphere to another atomic state with energy ζ localizing at an majority

Fig. 3.

impurity atom belonging to another sphere. As seen from Fig. 3, the above condition is written by

$$\frac{N_{\text{maj}}}{N_{\min}} < (1 + 2^{-2/3})^3 \doteq 5 \quad (54)$$

Case (II). N_{maj} is much larger than $N_{\min}$, and it is convenient to divide the impurity atoms into molecules.

From the above consideration, we calculate the conductivity by the model that the steady current is determined by the inter-molecular transitions, and in this process, the majority impurity atoms locating within distance d from the surface of each molecule is important.

Concerning to $F(E)$, we can use Eq. (47) also in this case. Further, if the condition, $\zeta, E_0 \gg \kappa T$, is satisfied, we can replace E by E_0 , and thus $F(E)$ becomes as

$$F(E) \doteq F(E_0) = \frac{3\zeta^3}{E_0^4} N_{\min} \quad (55)$$

The range of the integration by E is defined by, $-\frac{E' E_0}{E' - E_0} \leq E \leq -E_0$, where E' is defined by

$$E' = e^2 / \epsilon_0 d. \quad (56)$$

On the other hand, the determination of $G(E, d)$ is fairly complicated. However, here, we assume it as constant for simplicity. Then $G(E, d)$ becomes

$$G(E, d) = \frac{E' - E_0}{E_0^2}, \quad (57)$$

and the range of the integration by d is defined by $0 \leq d \leq E_0 / E - E_0$.

From the above consideration, J_x is written by

$$J_x = e^2 F \frac{3\pi}{2} N_{\min} \eta \frac{d^2 D^2 \kappa \Theta \zeta^3 (E' - E_0)}{\hbar M u^2 E_0^6} \left(\frac{T}{\Theta} \right)^4 J_a^2 \\ \times \exp \left(\frac{E_0 E' / (E' - E_0) - \zeta}{\kappa T} \right) \varphi_3 \left(\frac{E_0^2}{\kappa T (E' - E_0)} \right) \quad (58)$$

where

$$\varphi_n^{(x)} = \int_0^x \frac{y^n dy}{e^y - 1} \tag{59}$$

$$\eta^{-1} = 1 - \left(1 - \frac{d}{d_{\min}}\right)^3 \tag{60}$$

The facror η is multiplied to extend the surface current to the total current.

The range where Eq. (58) is applicable may be determined by the condition that the potential energy of the surface range considered

Fig. 4.

in the above calculation is larger than the Fermi energy $-\zeta$, as is shown in Fig. 4. This condition is written by

$$N_{\text{maj}}/N_{\text{min}} > (1 + 2^{1/3})^3 \doteq 11.5 \tag{61}$$

The range $5 < N_{\text{maj}}/N_{\text{min}} < 11.5$ is not covered by the above cases. However, we can obtain a knowledge of this range by the extrapolation from the both sides.

§ 5. Comparison with Experimental Results

In this section, our results obtained in the preceding section are compared with the experimental results made by Fritze³⁾ for several samples of n- and p-type Germanium. The results are shown in Table I.

The first three samples are Sb-doped n-type Ge, and the next three are In-doped and the last three are Ga-doped p-type Ge. These

Table I. Theoretical and experimental results of both n- and p-type Germanium.

* To evaluate the value of Eq. (79) in [I], we assume that $V=E_0$ and $a_0=d$.

three samples of each kind of impurity atom are chosen to contain the minority impurity atom of the concentration about 10^{14} , 10^{15} and 10^{16} cc⁻¹, or the majority impurity atom of the concentration about 10^{15} , 10^{16} and 10^{17} cc⁻¹. The ratio of N_{maj} and N_{min} runs from 2 to 44. As mentioned in § 2, the effective mass m^* of p-type Ge or Si is not determined in the localized impurity level state, and in Table I we take m^*/m as 0.1 in order to get a good agreement with the experimental results. This value of m^*/m may be not so unreasonable.

Not with standing of our rough approximation, both in the absolute value and the temperature dependence of resistivity, we get a fairly good agreement with the experimental

results except the samples of highest impurity concentration. Especially, we must consider the fact that the overlapping integral depends sensitively on the values of m^* and d , and thus if d varies with the change of temperatures, the temperature dependence of the resistivity changes fairly markedly.

In samples of highest impurity concentration, that is Sb-19-3 and In-5, the overlapping integrals are nearly the order of unity, and thus the model adoped in this paper is not applicable. These samples are considered rather to belong to the range 2) in § 1 already considered in the preceding paper [I]. In fact, as seen from [I], if the conduction mechanism of the range 2) is dominant, the re-

sistivity does not depend on temperature in the temperature range of impurity conduction, and it is rather satisfactory with the experimental results as shown in Table I. In the absolute values of the resistivity, too, the theoretical values calculated using the Eq. (79) of [I] is rather satisfactory with experimental results as shown in the last line of Table I.

In the sample Ga-4-4, too, the overlapping integral is nearly the same order as that of Sb-19-5. Nevertheless, the experimental results show that in Ga-4-4 our model adopted in this paper is applicable in fairly good approximation rather than that of the range 2). This situation seems to cause from the fact that the ratio $N_{\text{maj}}/N_{\text{min}}$ is fairly large in Ga-

4-4, because the larger the ratio $N_{\text{maj}}/N_{\text{min}}$ becomes, the more stable our model of molecular system becomes. Thus, our model is applicable until higher concentration of impurity atom in order that the fluctuation of the local potential energy, that is $\zeta - E_0$, becomes larger.

In Si and the other substances, for example InSb, too, the theoretical calculations are performable. However, in these substances, the detailed experimental results such as Fritzsche's in Ge are not performed, and further the some parameters are lacking. Therefore, the detailed comparison with experimental results are not given in this paper.

Appendix I

We assume here that the Hamiltonian of electron-phonon interaction is written as

$$H_{ep} = D \left(\frac{\hbar}{2MNu} \right)^{1/2} \sum_q \sum_k \sum_n q^{1/2} C_{k+q} \{ e^{-i(k+q)R_n} a_k^* a_n (A_q + A_{-q}^*) + e^{i(k+q)R_n} a_n^* a_k (A_{-q} + A_q^*) \} \quad (\text{AI.1})$$

where D means the coupling constant, a_k^* , a_k and a_n^* , a_n mean respectively creation and annihilation operators of the electronic state ϕ_k of the conduction band and the localized state $\phi_{1s,n}$ and A_q^* , A_q mean respectively creation and annihilation operators of phonon with wave vector q of longitudinal mode. C_k is the Fourier component of the state ϕ_{1s} , that is

$$C_k = \int \phi_{1s}^*(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}} u_k(\mathbf{r}) d\mathbf{r}. \quad (\text{AI.1})$$

$\{\phi_k, \phi_{1s,n}\}$ compose a orthogonal set and ϕ_k is nearly represented by the Bloch function.

Electron can make a hopping from a localized state $\phi_{1s,n}$ to $\phi_{1s,m}$ by using the conduction state ϕ_k as the intermediate state. This process is represented by the second order perturbation of H_{ep} such as

$$\begin{aligned} H_{ep}^{(2)} = & (D^2 \hbar / 2MNu) \sum_{q_1} \sum_{q_2} \sum_k \sum_n \sum_m (q_1 q_2)^{1/2} C_{k+q_1} C_{k+q_2} e^{i(k+q_2)R_m - i(k+q_1)R_n} a_m^* a_n \\ & \times \{ a_k a_k^* (A_{-q_2} + A_{q_2}^*) (A_{q_1} / (E_k - E_n - \hbar\omega_1) + A_{-q_1} / (E_k - E_n + \hbar\omega_1)) \\ & + a_k^* a_k (A_{q_1} + A_{-q_1}^*) (A_{-q_2} / (E_k - E_m + \hbar\omega_2) + A_{q_2}^* / (E_k - E_m - \hbar\omega_2)) \}. \end{aligned} \quad (\text{AI.3})$$

This mechanism represents essentially a Raman Process, and not important in very low temperatures where the impurity conduction is important. The only important term amongst this process comes from the term $q_1 = q_2$. We consider for simplicity the absolute zero temperature, then this term becomes

$$\frac{D^2 \hbar}{2MNu} \sum_n \sum_m a_m^* a_n \left\{ \sum_k \sum_q \frac{q |C_{k+q}|^2 \exp i(k+q)R_{nm}}{E_k - E_n + \hbar\omega_q} \right\}. \quad (\text{AI.4})$$

In the denominator, we can neglect $\hbar\omega_q$ because it is always finitely positive. Further we can replace q approximately by k because in the summation of q , the main contribution comes from the terms in which $k+q$ is nearly zero. Then the summation by q is performed

easily and gives the overlapping integral between the localized states $\phi_{1s,n}$ and $\phi_{1s,m}$ that is J_{nm} . The summation by k is also performable and the above term is written approximately by

$$\frac{3}{8} \frac{D^2 \hbar q_0}{E_0 M u} J_{nm} \quad (\text{AI.5})$$

where E_0 means the energy width of the considering band, and q_0 is the Debye cut off wave vector. This term gives the correction of the overlapping integral J_{nm} and the correcting factor is nearly given by

$$\frac{3 D^2 \hbar q_0}{8 E_0 M u}, \quad (\text{AI.6})$$

where Δ is the ionization energy of the impurity state $\phi_{1s,n}$. In Ge, this correction factor is the order of 10^{-1} .

Appendix II

We consider the system where the identical particles of N numbers are contained per unit volume, and the probability to find a particle in a volume v is proportional to v . Then the probability to find n -particles in a fixed volume v is given by

$$W_n = \binom{N}{n} v^n (1-v)^{N-n} \quad (\text{AII.1})$$

As easily seen, W_n satisfies the condition

$$\sum_{n=0}^N W_n = 1 \quad (\text{AII.2})$$

When the conditions, $v \ll 1$, $n \ll N$ and $vn \ll 1$ are satisfied, W_n is approximated by

$$W_n = \frac{N^n}{n!} v^n e^{-v(N-n)} = \frac{1}{n!} x^n e^{-x} \quad (\text{AII.3})$$

where

$$x = Nv \quad (\text{AII.4})$$

Therefore, the probability to find more than two particles in a fixed volume v is given by

$$W_2 = 1 - W_0 - W_1 = 1 - (1+x)e^{-x} \quad (\text{AII.5})$$

For example, if we put $x=2$, W_2 becomes 0.61.

Next, we obtain the other probability, that is, the probability to find n particles in volume v and δn particles in a different volume δv , where δv is a arbitrary small volume. It is written by

$$W_n^{\delta n} = \binom{N}{n} v^n \binom{N-n}{\delta n} \delta v^{\delta n} (1-v-\delta v)^{N-n-\delta n} \quad (\text{AII.6})$$

or using the above mentioned conditions, and in limit of $\delta v \rightarrow 0$,

$$= W_n \frac{N^{\delta n}}{\delta n!} \delta v^{\delta n} \quad (\text{AII.7})$$

For example, if we put $\delta n=1$, and replace v and δv respectively by $(4\pi/3)r^3$ and $4\pi r^2 dr$ as shown in Fig. A1, the probability to find

Fig. 5.

$(n+1)$ -th neighbours particle in distance $r \sim r + dr$ from a given center is written by

$$W_n^r = 4\pi N r^2 \frac{x^n e^{-x}}{n!} dr, \quad (\text{AII.8})$$

and the average of r^t of $(n+1)$ -th neighbour's particle is

$$\langle r_{n+1}^t \rangle = 4\pi N \int_0^\infty r^{2+t} \frac{x^n e^{-x}}{n!} dr \quad (\text{AII.9})$$

$$= a_0^t \Gamma\left(n + \frac{t}{3} + 1\right) / n! \quad (\text{AII.10})$$

where

$$\frac{4\pi}{3} a_0^3 = N^{-1}, \quad (\text{AII.11})$$

and $\Gamma(x)$ is ordinary Γ -function. If we put $n=1$ and $t=3$, r^3 average of next nearest neighbour becomes $\langle r_2^3 \rangle = 2a_0^3$ or $x=2$.

Magnetic Property and Crystal Chemistry of Ilmenite (MeTiO_3) and Hematite ($\alpha\text{Fe}_2\text{O}_3$) System

II. Magnetic Property

By Yoshikazu ISHIKAWA*

Institute for Solid State Physics, University of Tokyo, Tokyo

and Syun-iti AKIMOTO

Geophysical Institute, University of Tokyo, Tokyo

(Received July 11, 1958)

Magnetic properties of synthesized solid solutions of ilmenite (MgTiO_3 , MnTiO_3 , FeTiO_3 , CoTiO_3 and NiTiO_3) and hematite ($\alpha\text{Fe}_2\text{O}_3$) are investigated and it was confirmed that those of any ilmenite-hematite series can be divided into three parts: i) pure ilmenite, ii) solid solutions with $R\bar{3}$ crystal symmetry and iii) those with $R\bar{3}c$ crystal symmetry. Pure ilmenites are antiferromagnetics having their Néel temperature below 80°K except MgTiO_3 , the Néel temperature of MnTiO_3 being determined to be 41°K . The solid solutions with $R\bar{3}$ symmetry are ferrimagnetic except MgTiO_3 series which is paramagnetic. Ferrimagnetism in FeTiO_3 , CoTiO_3 and NiTiO_3 series is due to the same mechanism, while that in MnTiO_3 series to the different one. The solid solutions with $R\bar{3}c$ symmetry are again antiferromagnetics on which feeble ferromagnetism is superimposed.

Through the analysis of magnetic properties of ferrimagnetic specimens, the sign of superexchange interaction with the coupling angle ($\angle\text{Me-O-Me}$) of 90° in the rhombohedral structure was determined.

§ 1. Introduction

In the previous paper¹⁾ we have discussed the crystallographic problem in the solid solution of ilmenite (MeTiO_3) and hematite ($\alpha\text{Fe}_2\text{O}_3$) and showed that the miscibility of ilmenite and hematite in the solid solution varies with different ilmenite-hematite systems. That is, FeTiO_3 and NiTiO_3 make the solid solution with Fe_2O_3 in the whole range of composition, while in the solid solution of hematite and MgTiO_3 , MnTiO_3 or CoTiO_3 , there exists immiscible range of composition. It has also been established that, in any cases, the solid solutions on the ilmenite side and hematite side have different crystal symmetries, i.e. $R\bar{3}$ and $R\bar{3}c$ respectively.

In this paper we shall discuss the magnetic properties of these solid solution systems. As we reported in previous paper of the solid solution of FeTiO_3 and Fe_2O_3 ²⁾ magnetic properties of the solid solutions are greatly correlated with their crystal symmetry and

can be divided into three parts; i) antiferromagnetism of pure ilmenite, ii) ferrimagnetism of specimens with $R\bar{3}$ symmetry and iii) antiferromagnetism for specimens with $R\bar{3}c$ symmetry on which parasitic ferromagnetism is superimposed.

The investigations of magnetic properties in the solid solution have different significances for these three parts, which are discussed separately in the following.

i) Pure ilmenite, which we shall use as a generalized name of substances with the ilmenite structure such as FeTiO_3 , NiTiO_3 , MnTiO_3 , CoTiO_3 and MgTiO_3 in this paper is found to be antiferromagnetics with their Néel temperature below 80°K except MgTiO_3 . Antiferromagnetism of FeTiO_3 was first found by Bizette and Tsai³⁾ and its antiferromagnetic structure was determined by Shirane et al. by a neutron diffraction analysis⁴⁾. According to their results, magnetic structure of FeTiO_3 is constructed by two kinds of superexchange interactions between magnetic ions. One is that in a hexagonal layer of which coupling angle ($\angle\text{Me}^{2+}\text{-O}^{2-}\text{-Me}^{2+}$) is

* Department of Applied Physics, Faculty of Engineering, University of Tokyo.

nearly 90° and the other is that between magnetic ions on different layers which are separated by two oxygen layers. Such interactions have formerly been neglected as weak ones, but recently much attention has come to be paid on. For example, it has been reported that in chlorides of transition metals⁵⁾ or in a zinc ferrite⁶⁾ such interactions as stated now play an important role in constructing the magnetic structure. Through the investigation of magnetic properties of ilmenites, we can obtain some knowledge about these interactions in the rhombohedral structure.

ii) The solid solutions with the crystal symmetry $R\bar{3}$ are found to be ferrimagnetic except $MgTiO_3$ series. These ferrimagnetic substances are of the rhombohedral structure and do not belong to any groups of the ferrimagnetic oxides hitherto investigated. This ferrimagnetism was first found in the solid solution of $FeTiO_3$ and Fe_2O_3 by Nagata et al. in nature⁷⁾. Since then, detailed investigations have been carried out on this solid solution series and results are reported in the previous papers.^{2), 8), 9)} Although we have showed in these papers that the ferrimagnetism is interpreted qualitatively by the theory proposed by Néel if the proper arrangement of cations is assumed, several points are left unexplained. Furthermore it has been expected that in $FeTiO_3$ series the situation that Fe^{2+} ions are unstable at high temperature and their orbital moments are left unquenched may complicate the magnetic properties of this series. It is, therefore, necessary for the purpose of understanding the ferrimagnetism newly discovered to extend our investigation to isomorphic compounds such as the solid solution series of $CoTiO_3$ - Fe_2O_3 , $MnTiO_3$ - Fe_2O_3 and $NiTiO_3$ - Fe_2O_3 and to distinguish the properties common to all the solid solution series from those peculiar to each series.

iii) The solid solutions with the crystal symmetry $R\bar{3}c$ are antiferromagnetics on which a feeble ferromagnetism is superimposed. It is confirmed that the antiferromagnetism and the feeble ferromagnetism in the solid solutions are due to the same origin with those in hematite. Although the antiferromagnetism in hematite is easily under-

stood by its cations arrangement and the superexchange interactions between them^{10), 11)} no decisive interpretation has yet been done on the feeble ferromagnetism. Besides, the change of anisotropy below $260^\circ K$ in hematite¹²⁾ is also left unexplained. We have showed in the previous paper¹⁾ that the solid solutions with $R\bar{3}c$ symmetry have entirely the same crystal structure as hematite. Hence we can substitute Fe^{3+} ions in hematite by other cations such as Mg^{2+} , Mn^{2+} , Co^{2+} , Fe^{2+} , Ni^{2+} and Ti^{4+} for the wide range of composition without changing its crystal symmetry by preparing the solid solutions of hematite and ilmenite with these cations. Such a substitution produces a change in the magnetic couplings in hematite continuously and may throw some light on the above-mentioned magnetic properties of hematite.

A. Experimental Results

In the following sections magnetic properties of the ilmenite and hematite system are studied in conformity with the three classifications mentioned in the introduction. All specimens used were prepared in the ceramic forms. The methods for preparing them are described in the previous paper.¹⁾

§ 2. Magnetic Properties of Ilmenite

The magnetic susceptibilities of ilmenites ($FeTiO_3$, $MnTiO_3$, $CoTiO_3$ and $NiTiO_3$) are measured with the aid of a magnetic balance. It was confirmed that they are paramagnetic above $80^\circ K$ and their magnetic susceptibilities obey the Curie-Weiss law $\chi_M = C_M / (T - \theta)$ above room temperature. The values of θ and μ_{eff} calculated from C_M are presented in Table I. The magnetic susceptibilities below $80^\circ K$ was measured for $FeTiO_3$ and $MnTiO_3$ at the Research Institute for Iron, Steel and other Metals, Tôhoku University* and both are found to become antiferromagnetic at low temperature. The result for $FeTiO_3$ has already been reported²⁾ and that for $MnTiO_3$ is shown in Fig. 1. From this figure the Néel point of this substance is determined to be $41^\circ K$. Although measurements have not yet been extended below $80^\circ K$ for other ilmenites, we can expect, with sufficient plausibility, that other two ilmenites may also

* The authors are entirely indebted to Dr. Tsukawaka for the measurements.

Table I. Magnetic properties of ilmenite.

Substance	$T_m(K)$	C_{Mol}	$\Theta (^{\circ}K)$	μ_{eff}	$\sqrt{4S(S+1)}$	$\sqrt{L(L+1)+4S(S+1)}$
FeTiO ₃	55°	3.92	17	5.62	4.90	5.50
NiTiO ₃		1.30	- 55	3.24	2.87	4.49
CoTiO ₃		3.30	- 15	5.17	3.87	5.21
MnTiO ₃	41°	4.15	-210	5.80	5.92	5.92

Fig. 1. Magnetic susceptibility *vs.* temperature for MnTiO₃.

become antiferromagnetic below 80°K. In Table I, it must be noticed that FeTiO₃ has a positive value of Θ , while that of MnTiO₃ is negative and very large compared with those of other ilmenites. In the table we also show the values of μ_{eff} calculated from the formulae $\mu_{eff}=\sqrt{4S(S+1)}$ and $\mu_{eff}=\sqrt{L(L+1)+4S(S+1)}$ where L and S are the orbital and spin angular momentum quantum number respectively. From these values we expect that in MnTiO₃ the orbital moment is completely quenched and in NiTiO₃ and CoTiO₃ it is left slightly unquenched, while in FeTiO₃ it is left highly unquenched. The effective g factor of NiTiO₃ obtained from a measurement of paramagnetic resonance absorption is 2.22₆ which accords well with the above situation.*

§ 3. Magnetic Properties of Solid Solutions with $R\bar{3}$ Symmetry

It has already been reported that the solid solutions of FeTiO₃ and NiTiO₃ series are ferrimagnetic in this range.^{2),13)} In this sec-

* The measurement was carried out by Mr. Shimada in Institute for Solid State Physics, University of Tokyo.

tion we show the results for MnTiO₃ and CoTiO₃ series.

3.1. Intensity of magnetization

The intensity of magnetization was measured by the same method as that previously reported. In Figs. 2 and 3, thermomagnetic curves of several specimens MnTiO₃ and

Fig. 2. Intensity of magnetization in a field strength of 8500 Oe. *vs.* temperature for the specimens with $R\bar{3}$ symmetry of MnTiO₃-Fe₂O₃ system.

Fig. 3. Intensity of magnetization in a field strength of 8500 Oe. *vs.* temperature for the specimens with $R\bar{3}$ symmetry of CoTiO₃-Fe₂O₃ system.

CoTiO₃ series measured down to liquid nitrogen temperature in a field strength of 8500 Oe. are shown. The specimens of both series are found to be ferrimagnetic at low tempera-

ture and the intensity of magnetization increases linearly with decrease of temperature. These situations are quite similar to those for NiTiO₃ and FeTiO₃ series.^{2), 13)} By making the detailed comparison, however, we can find the magnetic properties of MnTiO₃ series are considerably different from those of other series. This situation can be better understood by comparing Figs. 4 and 5, where the field dependence of magnetization at 80°K of specimens in the various series is given. As these figures show, the characteristics of the field dependence of MnTiO₃ series are quite different from those of other series, that is, the magnetizations of all specimens in MnTiO₃ series are far from saturation under the field strength of 8500 Oe., while for other series they are nearly saturated by this field strength when the content of ilmenite in the solid solution is less than 80 mol. per cent. It seems to be more reasonable to suppose that such a characteristics of the field dependence of MnTiO₃ series may indicate that a weak ferromagnetism is superimposed on the paramagnetism. In Fig. 6, estimated satu-

ration values of magnetization at 0°K of all ilmenite-hematite system with $R\bar{3}$ symmetry are drawn against the composition, which are expressed in the unit of the reduced Bohr magneton number (μ_B/μ_{M_0} , where $\mu_{Mn+2}=5$, $\mu_{Fe+2}=4$, $\mu_{Co+2}=3$ and $\mu_{Ni+2}=2$ respectively) for the convenience of comparison. These values are obtained by extrapolating the values at 80°K to 0°K by the method previously reported.²⁾ In the case of FeTiO₃ series only the results for annealed specimens are shown. In the figure, the results of Bozorth et al. for FeTiO₃ series which were obtained by the measurements at 1.3°K in the field strength of 11000 Oe. are also plotted.¹⁴⁾ Their results accord fairly well with ours except that of 0.8 FeTiO₃·0.2 Fe₂O₃, for such a composition range our method of extrapolation is expected to include a considerable error. Although our results are only approximate ones and only a few data could be obtained for CoTiO₃ series because of the narrowness of the $R\bar{3}$ region in CoTiO₃ series, we may safely suppose from the figure that the ferrimagnetism in NiTiO₃ and CoTiO₃ is nearly the same as that in FeTiO₃ series, while that in MnTiO₃ series is greatly different. We shall show in the later section that such a difference may be attributed to the situation that MnTiO₃ has a different antiferromagnetic structure from other ilmenites.

3.2. Magnetic susceptibility

In the previous papers we have reported that the magnetic susceptibilities of NiTiO₃ series at high temperatures obey of Curie-Weiss law

$$\chi_M = \frac{C_M}{T + \Theta}$$

and C_M and Θ change continuously from those of Fe₂O₃ to those of NiTiO₃,¹³⁾ while in the case of FeTiO₃ series the anomalous change was observed.²⁾ In Fig. 7 the reciprocal of the magnetic susceptibilities of 0.8MnTiO₃·0.2Fe₂O₃ and 0.8CoTiO₃·0.2Fe₂O₃ is shown. In both cases their modes are similar to those of ordinary ferrimagnetics and the Curie constant C_M obtained from the straight line part in the figure by the least mean square method is turned out to be 5.90 for MnTiO₃ series and 3.30 for CoTiO₃ series respectively. It must be noticed that in the case of 0.8CoTiO₃·0.2Fe₂O₃ the value of C_M calculated by assuming the orbital moment is completely quenched is 3.16, which may indicate, in reference to the result in Table I, that the orbital moment which is left unquenched in pure CoTiO₃ is more quenched in the solid solution. The same situation may be expected in the solid solution of FeTiO₃ and the decrease in C_M in this series may, to some extent, be attributed to this effect.

§ 4. Magnetic Properties of Ilmenite-Hematite System with $R\bar{3}c$ Symmetry

All specimens investigated are found to be feebly ferromagnetic in this range. The thermomagnetic curves measured in a field strength of 8500 Oe. of MnTiO₃ series and MgTiO₃ series are shown in Figs. 8 and 9, and the intensity of magnetization at room temperature in the field strength of 8500 Oe. is plotted against the composition in Fig. 10. From this figure, we can find the intensity of

Fig. 7. Reciprocal magnetic susceptibility vs. temperature for the specimens of 0.8MnTiO₃·0.2Fe₂O₃ and 0.8CoTiO₃·0.2Fe₂O₃.

Fig. 8. Intensity of magnetization in a field strength of 8500 Oe. vs. temperature for the specimens with $R\bar{3}c$ symmetry of MnTiO₃-Fe₂O₃ system.

magnetization of the feeble ferromagnetism decreases linearly with increase in the content of MnTiO₃ from that of the parasitic ferro-

Fig. 11. Thermomagnetic curve at low temperatures of the specimens of MgTiO₃-Fe₂O₃ system of which composition deviates slightly from αFe₂O₃.

magnetism in Fe₂O₃. As the parasitic ferromagnetism is greatly affected by the atmosphere under which the specimen is prepared, all specimens are prepared in the same atmosphere. It must also be noticed in the figure that the rate of decrease is the same for both MnTiO₃ and MgTiO₃ series, which indicate that Mn²⁺, Mg²⁺ and Ti⁴⁺ do not contribute at all on the feeble ferromagnetism and the parasitic ferromagnetism of hematite are only diluted by these ions. In Fig. 11, we show the intensity of magnetization at low temperature of the specimens in MgTiO₃ series, whose composition deviates slightly from Fe₂O₃. Here we pay an attention to the low temperature transition of the parasitic ferromagnetism found by Morin.¹⁵⁾ As we found in the figure this transition temperature which is confirmed to exist in pure hematite is shifted by about 50°C to the low temperature side when only two mol per cent of MgTiO₃ is added to Fe₂O₃. Furthermore such a transition almost disappears when the content of MgTiO₃ exceeds 5 mol per cent. The entirely similar phenomenon is observed for MnTiO₃ series. In the case of FeTiO₃ series the situation is expected to be the same, for which we found as was reported in the previous paper²⁾ that the specimen of 0.93Fe₂O₃-0.07FeTiO₃ does not show any low temperature transition above 80°K.

§ 5. Summary of Experimental Results on Magnetic Properties of Ilmenite-Hematite System

In the above sections we have described the magnetic properties of the MnTiO₃, CoTiO₃ and MgTiO₃ series. These results, together with those of FeTiO₃ and NiTiO₃ series reported previously, are summarized as follows.

1) All ilmenites except MgTiO₃ are expected to be antiferromagnetics having the Néel temperature below 80°K. The magnetic structures of CoTiO₃ and NiTiO₃ are expected to be the same as that of FeTiO₃ which has been determined by the neutron analysis, while MnTiO₃ may have a different structure from those of other ilmenites.

2) The solid solutions of any MeTiO₃ and Fe₂O₃, xMeTiO₃-(1-x)Fe₂O₃ have a remarkable characteristic that the magnetic properties of the specimens on the ilmenite side

are considerably different from those on the hematite side. The former is ferrimagnetic at low temperature except in the case of MgTiO_3 series which is paramagnetic in this region, while the latter is antiferromagnetic on which the feeble ferromagnetism is superimposed. These characteristics are correlated with the situation that the crystal symmetries of both sides in the solid solutions are different with each other. The ferrimagnetism occurs only in the specimen having the crystal symmetry $R\bar{3}$, that is only in the specimen where Me^{2+} and Ti^{4+} ions are arranged in order, while the antiferromagnetism in the specimen with the crystal symmetry $R\bar{3}c$ where all cations are distributed at random among the lattice sites.

3) All ferrimagnetic specimens have a common characteristic that the magnetization increases almost linearly down to the liquid nitrogen temperature with decrease of temperature, indicating that molecular fields acting on the magnetic ions in these compounds are relatively weak.

4) The mechanism of occurrence of the ferrimagnetism is expected to be the same for FeTiO_3 , CoTiO_3 and NiTiO_3 series. By analyzing the results of FeTiO_3 series for which the most reliable data have been obtained, we can find the mechanism of ferrimagnetism of this group is different in the following four regions of composition.

i) The region where the magnetization is very weak and the magnetic structure is expected to be antiferromagnetic as a whole on which the feeble ferromagnetism is superimposed, which is $1 > x \geq 0.95$ for FeTiO_3 series, $1 > x \geq 0.9$ for NiTiO_3 and CoTiO_3 series.

ii) The region where the magnetization at 8500 Oe. increases abruptly with the increase of the content of hematite in the solid solution. The maximum value of magnetization in this region is most close to the value calculated by assuming that all magnetic moments on each layer in the compound are aligned in the same direction, coupling antiferromagnetically with those on the adjacent layer. This region is $0.95 > x \geq 0.8$ for FeTiO_3 series, $0.9 > x \geq 0.8$ for NiTiO_3 and CoTiO_3 series.

iii) The region where the saturation value of magnetization takes the value lower than

the one calculated by adopting the above assumption, which is $0.8 > x > 0.5$ for FeTiO_3 series and $0.8 > x \geq 0.7$ for NiTiO_3 series.

iv) The region where the saturation value of magnetization decreases sharply to zero with the further increase of the content of hematite in the solid solution, corresponding to the situation that the crystal symmetry $R\bar{3}$ in which Me^{2+} and Ti^{4+} ions are orderly arranged is changed into the symmetry $R\bar{3}c$ in which all ions are arranged at random, which is $0.5 \geq x \geq 0.45$ for FeTiO_3 series and $0.7 \geq x > 0.6$ for NiTiO_3 series.

5) On the contrary to the above situation the ferrimagnetism in MnTiO_3 series is caused by an origin common to whole composition range, which may be classified into i) of the above group. That is, the magnetization of all specimens of this solid solution series is very weak and it is far from saturation in the field strength of 8500 Oe.

6) The magnetization of the ferrimagnetic specimen in FeTiO_3 series is much affected by the heat treatment, while those of other solid solution series are not affected at all by the heat treatment.

7) The intensity of magnetization of the parasitic ferromagnetism in the antiferromagnetic specimen decreases with the increase of the content of MeTiO_3 in hematite, usually attaining to a minimum value for x around 0.4.

8) The low temperature transition of the parasitic ferromagnetism which is observed at 260°K for pure hematite is considerably shifted to the lower temperature side by addition of a small amount of MeTiO_3 in hematite. This transition disappears when the content of MeTiO_3 is increased more than five mol percent in the solid solution.

9) The magnetic susceptibility of the ferrimagnetic specimens in FeTiO_3 series shows a peculiar behavior, that is the value of C_M decreases and the value of θ in $\chi = C_M / T - \theta$ increases in keeping its positive sign as the composition changes from $x=1$ to $x=0.5$. Such a situation could not be observed for other solid solution series, that is the value of C_M obtained for these solid solution series can be interpreted by assuming that only spins contribute to the magnetic moment and the values of θ are negative for the whole range of composition.

B. Discussions

As we have described in detail in the previous papers^{1),2)} cation sites in the rhombohedral sesquioxide can be divided into four sublattices A_1 , A_2 , B_1 and B_2 and three types of superexchange interaction, Γ_a , Γ_b and Γ_c between magnetic ions on these sites have been expected to predominate in the structure. The former two are between magnetic ions on adjacent layers and the latter between ions on the same layer. The coupling angle $\angle\text{Me-O-Me}$ is greater for the former than the latter. In order to describe the magnetic structure of pure ilmenite, it is more appropriate to divide the sublattices A_1 and A_2 into four sublattices A_1 , A_2 , A_1' and A_2' as is shown in Fig. 12. In the following sections

antiferromagnetic arrangement of Me^{2+} ions is constructed by two kinds of superexchange interactions. One is that between A_1 and A_2 or A_1' and A_2' ; (Γ_c) and the other is that between A_1 or A_2 and A_1' or A_2' . We can easily find that three kinds of antiferromagnetic structure are possible in ilmenite, which are as follows;

- (a) A_1+ , A_2+ , $A_1'-$, $A_2'-$
- (b) A_1+ , A_2- , $A_1'+$, $A_2'-$
- (c) A_1+ , A_2- , $A_1'-$, $A_2'+$

where $+$ and $-$ indicate the directions of spins on the lattice site. Through the neutron analysis carried out by Shirane et al. the antiferromagnetic structure of FeTiO_3 was determined to be the case (a).⁴⁾ The spins are directed along c -axis in it. Hence we may decide that the sign of the superexchange interaction within the layer (Γ_c) is positive in FeTiO_3 . Although nothing is known about the antiferromagnetism in other ilmenites we can suppose their configurations through the magnetic studies of the solid solution. Because, as we state in detail in the next section, the structures (a), (b) and (c) grant different situations for the magnetic property of the solid solutions. We expect that NiTiO_3 and CoTiO_3 belong to the case (a), while MnTiO_3 to (b). If such an expectation is correct, we may obtain a knowledge about the sign of the superexchange interaction with the coupling angle 90° , the results being indicated in Table II.

§ 7. Ferrimagnetism in the Solid Solution

- (a) $1 > x \geq 0.45$ for FeTiO_3 series
- $1 > x > 0.6$ for NiTiO_3 series
- $1 > x \geq 0.8$ for CoTiO_3 series
- (b) $1 > x \geq 0.7$ for MnTiO_3 series

In this region the ordering of Me^{2+} and Ti^{4+} established in pure ilmenite is retained. Hence Me^{2+} and Ti^{4+} ions are expected to occupy the A and B sublattices respectively, while Fe^{3+} ions distribute at random among all sublattices. If, then, we assume that the intractions Γ_a and Γ_b are negative and their strength is fairly large compared with Γ_c , the magnetic momets on each layer are oriented in the same direction, coupling antiferromagnetically between those on the adjacent layers. Consequently the saturation magnetization of the solid solution, $x\text{MeTiO}_3-(1-x)\cdot$

Fig. 12. Cation lattice in a rhombohedral sesquioxide. A- sublattice must be further divided into two sublattices, A and A' in order to describe the antiferromagnetic structure in ilmenite.

magnetic properties of ilmenite and hematite system will be discussed by using these sublattices and superexchange interactions.

§ 6. Antiferromagnetism in Ilmenite

In ilmenite (MeTiO_3) Me^{2+} and Ti^{4+} ions occupy A and B sublattice selectively. As Ti^{4+} ions have no magnetic moments, the

Fe_2O_3 at 0°K is given by

$$J_s = J_A - J_B = x\mu_{\text{Me}^{2+}}$$

where J and μ_{Me} are the magnetization per one molecule of the solid solution and that of Me^{2+} ions respectively expressed by the number of Bohr magnetons. In Fig. 6 of the section 3, this value is drawn by a straight solid line. As is seen in the figure the estimated saturation values of the magnetization of the solid solutions deviate considerably from this line. As the ferrimagnetism of ilmenite and hematite system is divided into two groups, (a) FeTiO_3 , CoTiO_3 and NiTiO_3 series and (b) MnTiO_3 series, the deviation from this line is discussed separately for these two groups.

(a) *Ferrimagnetism in FeTiO_3 , CoTiO_3 and NiTiO_3 series*

As the magnetic properties of this group is represented by those of FeTiO_3 series which had been discussed in detail in the previous paper²⁾, the ferrimagnetism in four regions of this group is discussed only qualitatively in this section.

i) When the amount of Fe^{3+} ions which enter into the B sublattice is very small and the interaction between cations on the A and B sublattices are too weak to destroy the antiferromagnetic coupling between those on A and A' sublattices, the spin orientations of cations which enter into the B_1 sublattice are opposite to those of cations on the B_2 sublattice by the reason stated in (b) of this section. Consequently if Fe^{3+} ions are distributed at random among these two sublattices, the resultant spin configurations become antiferromagnetic and the difference in the occupation number between B_1 and B_2 sublattice produces a feeble ferromagnetism. As the interaction between the cations on the A and A' sublattices is very weak compared with that between the cations on the A and B sublattices, the region i) is expected to be very narrow if the interaction within the A or A' sublattices, that is I_a , is ferromagnetic.

ii) When the amount of magnetic ions on the B sublattice is increased, the antiferromagnetic coupling between the A and A' sublattice is destroyed by the strong interactions between A and B or B and A' sublattices and the magnetic moments on both A and A' sublattices began to align in the same direction,*

which results in the sharp increase in the resultant magnetizations with increase in Fe_2O_3 in the solid solution as is seen in Fig. 6. The magnetization of the specimen of $0.8\text{FeTiO}_3\text{--}0.2\text{Fe}_2\text{O}_3$ attains nearly to the value which is expected when the magnetic moments on A and B sublattices are aligned in the same direction, coupling antiferromagnetically with one another.

iii) When the content of Fe^{3+} ions in the solid solution is further increased the resultant magnetization comes to deviate from the value expressed by $J = x\mu_{\text{Me}}$ in spite of the fact that the interaction between A and B sublattices is more increased than that in the region ii). This situation can be interpreted if we put an assumption that the sign of the superexchange interaction with 90° angle I_c between Fe^{2+} and Fe^{3+} is negative. This assumption does not seem unacceptable, since we have expected in the above section that the superexchange interaction I_c between Fe^{2+} and Fe^{2+} is positive while between Fe^{3+} and Fe^{3+} is negative. Accordingly when the content of Fe^{3+} ions on the A sublattice is increased, negative superexchange interaction is predominant over positive one on the A sublattice. On the other hand, more than half of B sublattice sites are occupied by non-magnetic ions and then the magnetic coupling between the A and B sublattices is expected to be fairly weak. Such a situation results in a non-saturation of magnetization or a magnetic coupling at an angle on the A sublattice as was theoretically treated by Néel¹⁶⁾ and Yafet and Kittel¹⁷⁾ and found by Prince in CuCr_2O_4 through the neutron diffraction analysis¹⁸⁾. Hence the resultant magnetization deviates from the line $J = x\mu_{\text{Me}}$. It has been confirmed through the neutron diffraction analysis that magnetic moments are aligned in the planes perpendicular to c -axis in the solid solution of FeTiO_3 and Fe_2O_3 ¹⁹⁾. As the anisotropy energy within the layer is expected to be very weak in the rhombohedral oxide,^{20), 21)} the magnetic moments may easily rotate in the plane. Such a situation is very favourable for the coupling of magnetic moments at an angle.

iv) With the further increase of Fe_2O_3 content, the magnetization decreases rather sharply, attaining to zero in both FeTiO_3 and NiTiO_3 series. This corresponds to the situa-

* see note added.

tion that the perfect ordering of Me^{2+} and Ti^{4+} ions which we assumed in the above consideration is difficult to be maintained even in an annealed specimen⁹⁾ and the crystal symmetry changes from $R\bar{3}$ to $R\bar{3}c$ gradually in this region. As the range of $R\bar{3}$ is narrower for NiTiO_3 series than for FeTiO_3 series, the magnetization at 0°K begins to decrease at the lower content of Fe_2O_3 for NiTiO_3 series.

(b) *Ferrimagnetism in MnTiO_3 series*

The ferrimagnetism of the $\text{MnTiO}_3\text{-Fe}_2\text{O}_3$ series is greatly different from that of other series. As we can find in Fig. 6 the deviation of the saturation magnetization of MnTiO_3 series from the value $J=5x$ is so great that we can not attribute the mechanism of the ferrimagnetism in this series to the same one as that of (a) group.

We have found that such a magnetic property of MnTiO_3 series can be interpreted successfully if we assume that the superexchange interaction between Mn ions within a layer is negative. Such an assumption was expected from the fact that MnTiO_3 has large negative value of θ .

In order to explain the magnetic properties of this series, we consider the molecular field $\vec{h}_{B_1}$ or $\vec{h}_{B_2}$ which act on a magnetic ion on B_1 or B_2 sublattice sites. The A sublattice must be divided into four sublattices A_1 , A_2 , A_1' and A_2' as we show in Fig. 12. Then $\vec{h}_{B_1}$ and $\vec{h}_{B_2}$ are expressed as follows by using the same notation as we used in the previous paper.²⁾

$$\begin{aligned}\vec{h}_{B_1} &= 2/(\text{Ng}^2\mu_B^2)[3\Gamma_a\vec{J}_{A_1} + 3\Gamma_b\vec{J}_{A_2} \\ &\quad + 3\Gamma_a\vec{J}_{A_1'} + \Gamma_a\vec{J}_{A_2'}] \\ \vec{h}_{B_2} &= 2/(\text{Ng}^2\mu_B^2)[3\Gamma_a\vec{J}_{A_2} + 3\Gamma_a\vec{J}_{A_2'} \\ &\quad + 3\Gamma_b\vec{J}_{A_1'} + \Gamma_a\vec{J}_{A_1}]\end{aligned}\quad (1)$$

where $\vec{J}_{A_1}$, $\vec{J}_{A_2}$, $\vec{J}_{A_1'}$ and $\vec{J}_{A_2'}$ are the magnetic moments on the A_1 , A_2 , A_1' and A_2' sublattices respectively. The last term may be neglected as we stated in that paper.²⁾ The interaction between the B_1 and B_2 sublattices is also neglected because the number of magnetic ions on the B sublattice is small and probability that these magnetic ions form pairs is expected to be very small. We next put another assumption that the configuration of the magnetic moments on the A and A' sublattices is not altered by the interaction

between the A and B sublattices. In the cases of FeTiO_3 , CoTiO_3 and NiTiO_3 series, such an assumption was permitted only when the content of magnetic ions on the B sublattice is very small. On the other hand, in the case of MnTiO_3 series, such an assumption is permissible for a considerably wide range of content of the magnetic ions on the B sublattice. This is inferred from the situation that as the magnetic moments on the A and A' sublattice align antiferromagnetically within each sublattice, the magnetic ions on the B sublattice need not destroy the magnetic structure within the A and A' sublattices, because they tend to align the magnetic moments on both A and A' sublattices in the same direction through the negative interaction between B and A or A' sublattices. In the following we discuss the molecular field $\vec{h}_{B_1}$ and $\vec{h}_{B_2}$ in the three possible cases.

$$\text{i) } \vec{J}_{A_1} = \vec{J}_{A_2} = -\vec{J}_{A_1'} = -\vec{J}_{A_2'}$$

This is the case where the magnetic moments are coupled ferromagnetically within each A and A' sublattice, corresponding to the group (a). In this case the Eq. (1) is reduced to

$$\begin{aligned}\vec{h}_{B_1} &= 2/(\text{Ng}^2\mu_B^2) \cdot 3\Gamma_b\vec{J}_{A_2} \\ \vec{h}_{B_2} &= 2/(\text{Ng}^2\mu_B^2) \cdot 3\Gamma_b\vec{J}_{A_1'} = -\vec{h}_{B_1}.\end{aligned}\quad (2)$$

As this equation shows the direction of the magnetic moment on the B_1 sublattice is opposite to that on the B_2 sublattice. Hence if these two sublattices are occupied by the magnetic ions with an equal probability, the structure is antiferromagnetic as a whole, and a slight difference in the probability produces a weak ferromagnetism. Such a situation may be realized when a very small amount of Fe^{3+} ions is added to FeTiO_3 , NiTiO_3 or CoTiO_3 . This may correspond to the region i) of the group (a) in the section 5.

$$\text{ii) } \vec{J}_{A_1} = -\vec{J}_{A_2} = \vec{J}_{A_1'} = -\vec{J}_{A_2'}.$$

This is the case where the magnetic moments on the A_1 and A_2 or A_1' and A_2' sublattices are coupled antiferromagnetically, while those on the A_1 and A_1' or A_2 and A_2' sublattices ferromagnetically. In this case the Eq. (1) is reduced to

$$\begin{aligned}\vec{h}_{B_1} &= 2/(\text{Ng}^2\mu_B^2)(6\Gamma_a - 3\Gamma_b)\vec{J}_{A_1} \\ \vec{h}_{B_2} &= 2/(\text{Ng}^2\mu_B^2)(6\Gamma_a - 3\Gamma_b)\vec{J}_{A_2} = -\vec{h}_{B_1}.\end{aligned}\quad (3)$$

Again in this case the molecular fields on the B_1 and B_2 sublattices are opposite. Hence the situation becomes similar to the case i).

$$\text{iii) } \vec{J}_{a_1} = -\vec{J}_{a_2} = -\vec{J}_{a_1'} = \vec{J}_{a_2'}.$$

In this case the Eq. (1) is reduced to

$$\vec{h}_{B_1} = 2/(Ng^2\mu_B^2) \cdot 3\Gamma_2 \vec{J}_{a_2}$$

$$\vec{h}_{B_2} = 2/(Ng^2\mu_B^2) \cdot 3\Gamma_2 \vec{J}_{a_1'} = \vec{h}_{B_1}. \quad (4)$$

From this equation we can find that all magnetic moments which enter into the B sublattice align to the same direction. Then, a strong ferromagnetism is expected to appear and the resultant magnetization J_s of the solid solution $x\text{MnTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$ is given by

$$J_s = (1-x)J_B = 5(1-x). \quad (5)$$

We can find from these considerations that the solid solution of MnTiO_3 and Fe_2O_3 must exclusively belong to the case ii) and therefore find that the only permissible spin configuration in MnTiO_3 is (b) of the section 6, that is

$$A_1+, A_2-, A_1'+, A_2'-$$

where $+$ and $-$ means the spin directions on the sublattices. It may be possible to suppose that a tendency that Fe^{3+} ions occupy selectively one of two sublattices is increased when the content of Fe^{3+} ions in the B sublattice is increased. Accordingly the uncompensated magnetic moments are increased with increase in the content of Fe_2O_3 in the solid solution. Thus we can explain the magnetic properties of MnTiO_3 series. We hope that the situation we have expected is examined by the neutron diffraction analysis in near future.

§ 8. Superexchange Interaction with 90° Angle (Γ_2) in the Rhombohedral Oxide

In the above considerations we have shown that the superexchange coupling with 90° angle plays a very important role on the magnetic properties of the solid solution of ilmenite and hematite. In this section we summarize the results obtained from above considerations about the superexchange interaction, which are presented in Table II.

It has been reported that in the chloride of the transition metals the magnetic structure is chiefly determined by the superexchange interaction with 90° angle as in

ilmenite. The sign of its interaction is found by the neutron diffraction analysis to be positive in FeCl_2 , CoCl_2 and NiCl_2 ,²²⁾ while in MnCl_2 and FeCl_3 it is expected to be negative

Table II. The sign of the superexchange interaction with 90° angle in the rhombohedral oxides.

Configuration	Magnetic ions	sign
$(3d)^5-(3d)^5$	$\text{Fe}^{+3}-\text{O}-\text{Fe}^{+3}$	-
	$\text{Mn}^{+2}-\text{O}-\text{Mn}^{+2}$	-
$(3d)^6-(3d)^6$	$\text{Fe}^{+2}-\text{O}-\text{Fe}^{+2}$	+
$(3d)^7-(3d)^7$	$\text{Co}^{+2}-\text{O}-\text{Co}^{+2}$	+
$(3d)^8-(3d)^8$	$\text{Ni}^{+2}-\text{O}-\text{Ni}^{+2}$	+
$(3d)^5-(3d)^6$	$\text{Fe}^{+3}-\text{O}-\text{Fe}^{+2}$	-
$(3d)^5-(3d)^7$	$\text{Fe}^{+3}-\text{O}-\text{Co}^{+2}$	?
$(3d)^5-(3d)^8$	$\text{Fe}^{+3}-\text{O}-\text{Ni}^{+2}$	- (?)

in taking the sign of θ of the paramagnetic susceptibility into consideration.²³⁾ These results are very consistent with ours. Furthermore, Kanamori predicted in his theory of superexchange interaction that the interaction with 90° angle between $(3d)^5$ ions is negative, while positive for $(3d)^6$ under a cubic crystalline field.²⁴⁾ It has been reported that the sign of superexchange interaction is dependent not only on the numbers of electrons in the 3d shell but also on many other factors such as the orbital state of electrons which is determined by the symmetry of crystalline field.²⁴⁾ Although the crystal symmetry of the chlorides is slightly different from that of ilmenite, the orbital state of cations in ilmenite is expected to be not so different from that of chlorides. Hence our results which are obtained by an indirect method seems to be very reasonable.

§ 9. Magnetic Properties in the Solid Solution with $R\bar{3}c$ Symmetry

$0.5 \geq x \geq 0$	for FeTiO_3 series
$0.6 \geq x \geq 0$	for NiTiO_3 series
$0.4 \geq x \geq 0$	for MnTiO_3 series
$0.4 \geq x \geq 0$	for CoTiO_3 series
$0.5 \geq x \geq 0$	for MgTiO_3 series.

All specimens with $R\bar{3}c$ symmetry show the antiferromagnetism on which feeble ferromagnetism is superimposed. The antiferromagnetism in the specimen is easily under-

stood by their crystal structure, but as to the origin of the feeble ferromagnetism we can not deduce any decisive conclusion through our experiments. It is, however, expected that its origin must be the same as that in hematite, hence careful investigations of our series may be very profitable for understanding the parasitic ferromagnetism in hematite.

Among many hypotheses proposed to explain the feeble ferromagnetism in hematite, those by Li²⁵⁾ and Finch and Sinha²⁶⁾ seem to be the most plausible in the present stage. The one attribute the parasitic ferromagnetism to the uncompensated magnetization in the antiferromagnetic domain walls which is stabilized by some imperfections, while the latter suggest through their electron diffraction analysis that it is a ferrimagnetic deformation of Fe_2O_3 ($\beta\text{Fe}_2\text{O}_3$) precipitated in the form of the basal intergrowth with hematite ($\alpha\text{Fe}_2\text{O}_3$). In any cases, it may be safely said that the parasitic ferromagnetism owes its origin to some imperfections in the crystal.

We have found, as shown in Fig. 10, that the intensity of magnetization of the feeble ferromagnetism in the solid solution is decreased with increase of the content of ilmenite (FeTiO_3 , MnTiO_3 or MgTiO_3). This experimental results imply that the parasitic ferromagnetism is entirely inherent to Fe_2O_3 and does not related to such a crystalline defect as dislocations because the addition of MeTiO_3 is not expected to decrease systematically such a defect. Accordingly the suggestion of Finch and Sinha is very attractive to explain our experimental results. Detailed investigations are now going on along this line.

In Fig. 11 we showed that the low temperature transition in hematite is lowered with the addition of MeTiO_3 in it and disappears when the content of MeTiO_3 exceeds 5 mol. per cent. This result is nearly consistent with that of Haigh who measured the effect of addition of Al_2O_3 and TiO_2 in Fe_2O_3 .²⁷⁾ As the low temperature transition is closely related to the change of anisotropy, we may suppose that the addition of small amount of any impurities such as Ti^{4+} , Al^{3+} , Fe^{2+} , Mg^{2+} and Mn^{2+} is sufficient to suppress such a change.

In concluding the present paper the authors

wish to express their hearty thanks to Prof. Shozo Sawada and Prof. Takesi Nagata under whose guidance and encouragement the work of this series has been accomplished. Their thanks are also due to Dr. I. Tsubokawa for their magnetic measurement at liquid helium temperature, to Dr. G. Shirane for his neutron analysis and to Mr. Kondho for his illuminating discussions.

Note added

According to a recent communication from Dr. Shirane, it was confirmed through a neutron analysis that the long range magnetic order vanishes in a specimen of 0.9FeTiO_3 - $0.1\text{Fe}_2\text{O}_3$ even at 4°K , while broadly diffused scattering lines indicate the presence of short range order. The magnetic moment observed in a field strength of 8500 Oe. for this specimen must be due to that of the cluster.

It seems to be plausible that A-B or A'-B interactions, which are strong enough to destroy the antiferromagnetic A-A' interaction, are still insufficient to construct a long range magnetic order over the whole crystal in the specimen with this composition.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 11, NOVEMBER, 1958

The Temperature Dependence of Forced Magnetostriction

By Toshiro TSUJI*

*Department of Chemistry, Faculty of Science,
Kyoto University*

(Received July 31, 1951)

The forced magnetostriction above technical saturation was measured on some ferromagnetic materials at various temperatures, from the boiling point of oxygen to about 250°C. As expected theoretically, large forced magnetostriptions were observed either as the temperature approached up to the Curie point, or in the sample which has a considerable anomaly of thermal dilatation, such as alloys of invar system. The results obtained were discussed from the standpoint of thermodynamics. We also observed the magnetostriction at the temperature above the Curie point.

§ 1. Introduction

Small deformations of a ferromagnetic crystal in the presence of magnetic field are made up of three parts. The first depends merely on the shape of the sample, while the second is caused by the anisotropy of the spontaneous distortion. These two effects are observed at low and intermediate field strengths as the sample is magnetized through domain wall motion and by the rotation of magnetization vectors within domains. Beyond the technical saturation there is a different process of magnetization corresponding to the increase in saturation magnetization by external field. In the region of the apparent saturation the

sample still changes its dimensions linearly with external field. This deformation is called the forced magnetostriction, or the volume magnetostriction because of its nearly isotropic nature. The forced magnetostriction is closely connected with the anomaly in thermal dilatation. Both effects arise from the volume dependence of spontaneous magnetization.

Ferromagnetic expansion (or contraction) takes place with the appearance of the spontaneous magnetization. The magnitude of the distortion may be estimated by assuming a non-magnetic state below the Curie point. This state is not realized, but its dilatation curve is drawn by extrapolating the real curve in paramagnetic region into the lower temperature range. The difference of these two curves gives the spontaneous distortion. Thus estimated values attain the order of $10^{-3} \sim 10^{-4}$ in the relative change of length for ferromagnetic metals. The spontaneous distortion is

This paper was submitted to the Faculty of Science, University of Kyoto, in partial fulfillment of the requirements of the degree of Doctor of Science, July, 1958.

* Present address; Nippon Electric Company Ltd., Tokyo.

almost isotropic. Though the spontaneous distortion itself cannot be measured, its change with magnetic field is observable as the forced magnetostriction. This effect, so small as it is, has an importance in providing us a direct information on the nature of ferromagnetic coupling.

For this reason we have investigated the temperature dependence of the forced magnetostriction of some ferromagnetic materials. The experimental results are discussed from the standpoint of thermodynamics. It has been considered difficult to measure the small magnetostriction at various temperatures, but the difficulty is reduced by the use of strain gauge. At the same time we extended our measurements of the magnetostriction into the region above the Curie point.

§ 2. Theory of the Forced Magnetostriction

The fundamental relation of thermodynamics concerning magnetostriction at constant temperature is given as follows,

$$\left(\frac{\partial \omega}{\partial H}\right)_P = -\frac{1}{V_0} \left(\frac{\partial(VI)}{\partial P}\right)_H, \quad (1)$$

where V_0 and ω are the unit volume and its relative change. Using bulk modulus K ,

$$\left(\frac{\partial \omega}{\partial H}\right)_P = \frac{1}{KV_0} \left(\frac{\partial(VI)}{\partial \omega}\right)_H. \quad (2)$$

Let us consider the forced magnetostriction which is proportional to an increase in spontaneous magnetization with field. According to the molecular field approximation we can derive an expression for the volume effect,

$$\left(\frac{\partial \omega}{\partial H}\right) = \frac{1}{K} \frac{dW}{d\omega} \cdot I \left(\frac{\partial I}{\partial H}\right), \quad (3)$$

where W is the molecular field constant and $dW/d\omega$ means the variation of the exchange interaction with interatomic distance. If the forced magnetostriction is isotropic and sufficiently small, the relative change in volume can simply be obtained from the linear change.

In the equation (3) $d\omega/dH$ is proportional to $I(\partial I/\partial H)$, provided that both $dW/d\omega$ and K are considered to be constant. According to the molecular field theory $I(\partial I/\partial H)$ increases as the temperature approaches to the Curie point from below. Consequently we can observe large forced magnetostriction near the Curie point.

The experimental works on the temperature dependence were made by Kornetzki¹⁾ and

Döring²⁾. Their results have the same tendency consonant with the above argument, though the measurements were not carried out in wide temperature range. But in this simple theory a difficulty arises in determining the value of $dW/d\omega$. Néel³⁾ and other authors⁴⁾ tried to find this value. It was assumed that the small change in interatomic distance would merely give rise to the variation of exchange interaction without affecting the electronic structure of atom. Nevertheless the results obtained are unsatisfactory in that they contradict with each other; as shown in Fig. 1,

Fig. 1. Interaction curves relating the exchange energy to the distance D between atom centers, with fixed diameter d of $3d$ shell. (a) Bethe-Slater curve. (b) Néel's curve.

$dW/d\omega$ is negative for iron in Néel's interaction curve, but positive in Bethe-Slater's⁶⁾.

Using the molecular field approximation Néel gave the relation of the anomaly in thermal dilatation. This result reads as follows;

$$\lambda = \lambda_0(I/I_0)^2, \quad (4)$$

where λ and λ_0 are the relative change in length of spontaneous distortion at an arbitrary temperature and at 0°K , respectively. The analogous equation can be derived by integrating the equation (3) with regard to I , from 0 to I .

To visualize how the change in dimensions takes place with spontaneous magnetization, we employ the Ising ferromagnet which has

a magnetic moment of spin 1/2 at each lattice point. Two different interatomic distances are assumed for parallel and antiparallel configurations of nearest neighbour spins. Therefore the ordering process of spin gives rise to the change in dimensions. The anomaly in thermal dilatation is due to the spontaneous ordering below the Curie point. The forced magnetostriction corresponds to the field-induced-increase in the degree of order. The strong external field produces the spin ordering in the paramagnetic region. As far as the exchange interaction remains the magnetostriction can be observed even above the Curie point.

On this basis we calculated the mean relative change in length as a function of magnetization. The same equation as (4) was obtained when the Bragg-Williams approximation was used for spin arrangement (See Appendix I). The magnetostriction in the paramagnetic region can be expressed by simply replacing I by (χH) , as follows,

$$\lambda = \lambda_0 (\chi H / I_0)^2, \quad (5)$$

χ being the paramagnetic susceptibility.

In a rough estimation λ turns out to be more than 10^{-6} for a sample, $\chi = 2 \times 10^{-3}$ emu, $\lambda_0 = 5 \times 10^{-3}$ and $I_0 = 1000$ gauss, placed in the magnetic field of 10,000 oersteds. The relative change of the order of 10^{-6} can be easily detected in our experiments.

§ 3. Experimental Method

To investigate the temperature dependence of the forced magnetostriction the measurements were carried out at various temperatures from the boiling point of oxygen to 250°C . The upper limit means that of using the strain gauge, but it is sufficiently higher than the Curie points of some ferromagnetic materials.

In order to obtain a constant temperature higher than the room temperature we used an oil bath with a heater. The measurement at lower temperatures was made in the Dewar bottle containing cooling agents. These heat controllers have so large heat capacities that the measuring system is not sensible to slight thermal disturbances. A small sample and its holder were set, together with the heat controller, between the pole pieces of De Little type electromagnet. The distance between these pole pieces and their diameters are 3 cm

and 5 cm, respectively. A schematical diagram of the apparatus is shown in Fig. 2. With this arrangement we observed the magnetostriction up to the field strength of 23,000 oersteds.

Fig. 2. Schematic diagram of measuring apparatus.

In measuring the magnetostriction the strain gauge technique⁹⁾ has been used; the change in length was directly detected by the deflection of galvanometer composing an element of the Wheatstone Bridge circuit. The strain sensitivity of the order of 5×10^{-7} per mm scale can be obtained. Unfortunately the usual strain gauge coated by paper is not available at temperatures higher than 50°C . But the bakelite coated gauge enables us to employ it to 250°C . When we use the strain gauge at much higher temperatures special coating such as ceramic one is necessary.

The usual strain gauge made of the constantan alloy (Ni 44.5%, Cu 55.5%) has large magnetoresistance effect especially at lower temperatures. On the other hand we observed the negligible magnetoresistance effect for the strain gauge of the alloy containing 57% nickel, 16.5% chromium, 24% manganese and 2.5% molybdenum. This gauge was used in the measurement at lower temperatures.

§ 4. Results and Discussions

The anisotropy of the spontaneous distortion or magnetostriction constants can be determined by rotating a crystal in the strong magnetic field. In this state the forced magnetostriction superposes upon the spontaneous distortion. If the forced magnetostriction is

anisotropic the magnetostriction constants would be dependent on the field strength.

Sato⁷⁾ pointed out that the anisotropic term was important especially at lower temperatures. The large anisotropy was observed by Vautier⁸⁾ for iron single crystal. On the contrary we saw the small anisotropy in forced magnetostriction of 2.6% and 3.2% silicon steel⁹⁾. The similar results were previously obtained by Carr and Calhoun¹⁰⁾.

The magnetostriction in cubic crystal is described analytically by the following equation,

$$\lambda = h_0 + h_1 \sum_i \alpha_i^2 \beta_i^2 + h_2 \sum_{i>j} \alpha_i \alpha_j \beta_i \beta_j + \dots, \quad (6)$$

where the α_i 's and β_i 's are the direction cosines of magnetization and those of measured change in length with respect to the crystal

axes. Assuming that λ varies linearly with the external field, we can write all h_i 's as follows,

$$h_i = h_i^0 + h_i' H. \quad (7)$$

According to our previous data the anisotropic linear coefficients were extremely small for 2.6% and 3.2% silicon-steel. h_1' and h_2' were only a few percent of h_0' in our experiment. In consequence the volume change of the forced magnetostrictions is approximately equal to three times h_0' . Our previous results are cited again in Table I.

The forced magnetostriction is nearly isotropic, especially in the samples having cubic symmetry. Accordingly we used polycrystalline samples in the study of the temperature dependence. We can also estimate the order

Table I.

of magnitude of the forced magnetostriction from the differential form of equation (4),

$$\left(\frac{\partial \lambda}{\partial H}\right) = 2\lambda_0 \left(\frac{I}{I_0^2}\right) \left(\frac{\partial I}{\partial H}\right). \quad (8)$$

$(\partial I / \partial H)$ calculated from the molecular field theory is too small as compared with the observed value; for example, this is less than 10^{-5} for nickel, the observed one being 1.3×10^{-4} . Consequently, using the experimental values of λ_0 , I and $(\partial I / \partial H)$, we calculated the forced magnetostriction for nickel and iron, as indicated in Table I. These are in good agreement with our experiment.

Kornetzki¹⁾ observed the forced magnetostriction for iron between 0°C and 100°C while Döring²⁾ studied it for nickel near the Curie point. According to their results the forced

magnetostriction increases as the temperature approaches to the Curie point from below, but they did not study it at temperatures below 0°C and above the Curie point. In order to further the study of the temperature dependence in detaie, we measured the forced magnetostriction of the materials having comparatively low Curie temperatures.

It is well known that the invar alloys containing about 30~40% nickel have large anomaly in thermal dilatation. We selected as samples some of these alloys having comparatively low Curie temperatures such as 37% Ni-Fe ($\theta = 220^{\circ}\text{C}$) and 32% Ni-Fe ($\theta = 130^{\circ}\text{C}$). The samples were prepared by melting the mixed powder. Prior to melting the mixture was reduced in hydrogen gas atmosphere at 600°C for 1 hour. The small ingot was cold rolled

and cut into strips of size $1 \times 5 \times 10$ mm. The forced magnetostriction of these samples was measured at various temperatures as shown in Fig. 3. As expected theoretically large forced magnetostriction was observed.

We estimated the values of $(\partial\lambda/\partial H)$ at the

Fig. 3. Linear forced magnetostriction at various temperatures.
(a) 37% Ni-Fe. (b) 32% Ni-Fe.

Fig. 4. Temperature dependence of forced magnetostriction.

room temperature from the anomalies in thermal dilatation. The calculated values are cited in Table I. The values of $(\partial\lambda/\partial H)$ at various temperatures are plotted against the reduced temperature T/θ in Fig. 4. Although the relation (3) predicts a sharp increase of $(\partial\lambda/\partial H)$ near the Curie point, observed $(\partial\lambda/\partial H)$ varies linearly with temperature. The curves have a maximum a little below the Curie temperatures. Such a tendency is consistent with the observed temperature dependence of $I(\partial I/\partial H)$.

Recently Belov¹¹⁾ measured the change of spontaneous magnetization with linear stress σ for 36% Ni-Fe alloy. The temperature dependence of this change is shown in Fig. 5. It is in fair agreement with the temperature dependence of $(\partial\lambda/\partial H)$ in our experiment, as

Fig. 5. Temperature dependence of the change of spontaneous magnetization with linear stress for 36% Ni-Fe. (After Belov)

Fig. 6. Temperature dependence of forced magnetostriction.

well expected from the thermodynamical relation,

$$\left(\frac{\partial \lambda}{\partial H}\right)_{T,\sigma} = \left(\frac{\partial I}{\partial \sigma}\right)_{T,H} \quad (9)$$

Further we measured the forced magnetostriction of other ferromagnetic materials. Their temperature dependences are shown in Fig. 6. In cases of copper-nickel alloys and a Mn-Zn-ferrite, $(\partial \lambda / \partial H)$ is negative and its absolute value increases with temperature. From the data of the forced magnetostriction we can estimate the ferromagnetic contraction for Mn-Zn-ferrite to be of the order of 10^{-3} in relative change of length.

The magnetostriction in the region above the Curie point has scarcely been investigated up to the present. Using the samples of 32% and 37% nickel-iron alloys we measured the magnetostriction above their Curie points. The results obtained are shown in Fig. 7. At a

χ is not constant but decreases with the external field. It is natural to consider that the magnetostriction is proportional to the square of the field-induced-magnetization, χH .

From the equation (3) and the experimental data of the forced magnetostriction we get an information on the variation of the exchange interaction with interatomic distance. According to the molecular field theory it is easily seen that the signs of $(\partial \lambda / \partial H)$ and $(\partial W / \partial w)$ are the same. And the larger the forced magnetostriction the greater the variation of the exchange interaction. dW / dw thus calculated is consistent with the prediction by Bethe-Slater interaction curve for nickel and iron.

In conclusion the author acknowledges Professor H. Takaki for his kind guidance and encouragement throughout the work. The author also thanks Mr. Y. Nakamura and Mr. J. Hayashi for their instructive discussions. The expense involved in this research has been partly defrayed by the Scientific Research Expenditure of the Ministry of Education.

Appendix I

Let us consider a simple cubic crystal composed of N atoms. As mentioned in § 2, a length of the crystal containing $N_{\uparrow\uparrow}$ parallel and $N_{\uparrow\downarrow}$ antiparallel spin pairs is assumed to be proportional to

$$aN_{\uparrow\uparrow} + bN_{\uparrow\downarrow}$$

a and b being the lattice parameters corresponding to the two different spin configurations. According to the Bragg-Williams approximation,

$$\overline{N}_{\uparrow\uparrow} = \frac{zN}{4} \left\{ 1 + \left(\frac{I}{I_0} \right)^2 \right\}, \quad (A1)$$

and

$$\overline{N}_{\uparrow\downarrow} = \frac{zN}{4} \left\{ 1 - \left(\frac{I}{I_0} \right)^2 \right\}, \quad (A2)$$

where z is the number of nearest neighbour atoms and I_0 is the magnetization at 0°K. The magnetic expansion referred to the non-magnetic state is given by

$$\left(\frac{\delta l}{l}\right)_{\text{magnetic}} = \left(\frac{a-b}{a+b}\right) \left(\frac{I}{I_0}\right)^2. \quad (A3)$$

It is the same relation as Néel's, (4).

Diffusion Processes in Polymers under Irradiation; Polyvinyl Alcohol and CCl_4 System

By Tsutomu WATANABE

*Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo*

(Received June 20, 1958)

When the PVA film is irradiated in CCl_4 , PVA is swollen and cross-linked. A Phenomenological theory is proposed for this experiment. The processes are considered that with the change of diffusion constant CCl_4 enters into PVA as the radiation dose increases, and the radicals from CCl_4 react upon PVA and cause crosslinking. The results of calculation agree reasonably with experiments, that is, the weight changes of swollen polymers against the total dose, the gel fraction changes and the viscosity average molecular weight changes in sol fractions against the total dose. Other various mechanisms that can be considered are discussed.

§ 1. Introduction

On the irradiation effects on polymers, the diffusion processes of radicals or of gas molecules in polymers play sometime an important role, in many relations, such as does rate, temperature, sample thickness dependence of oxidation effect, of gas evolution effect, and of paramagnetic resonance absorption effect, etc. These phenomena have not been researched quantitatively from the standpoint of diffusion mechanism, but only discussed in qualitative views.

It has been known that the gel formation takes place in the aqueous solution of polyvinyl alcohol by irradiation¹⁾, but the similar experiment has not been carried out in the case of PVA-insoluble liquid systems. Recently Yoshitake²⁾ has discovered new experimental results that the gel of polyvinyl alcohol is obtained by irradiation in carbon te-

trachloride, or in dichlorbenzen. With 12.5 rad. sec⁻¹ of ⁶⁰Co gamma-ray dose rate, at room temperature, the polyvinyl alcohol film was irradiated in CCl_4 or in dichlorbenzen to the extent of $10^6 \sim 3 \times 10^7$ rad. Before irradiation, the PVA film was not swollen at all, but with increase of dose, the liquid molecules entered into PVA and the weight of film was increased. The weight change is so large ($\sim 30\%$ of the initial weight) that the entered molecule may be CCl_4 or dichlorbenzen. When this film was dried in vacuum in order that the entered molecules were made to get out of it, its weight came back to the value of unirradiated and the gel formation was detected from the results of gel fraction and viscosity measurements of its aqueous solution. And the relation between gel fraction and irradiation dose had not the tendency of Charlesby's curve³⁾. The detailed report of

these experimental methods and results, involving the measurements of other properties such as infra-red spectra, chemical analysis, etc. is to be published by Yoshitake before long.

These results are also concerned with the diffusion processes of liquid molecules being caused by irradiation. In this paper, the author proposed a phenomenological theory of this mechanism in PVA- CCl_4 system, obtained the results of calculation with some assumptions, and compared them with experimental data, and discussed other mechanisms that can be considered.

§ 2. Theoreticals of Swelling and Gel Fraction

A model of reaction mechanism is proposed as follows. When the PVA film is irradiated in insoluble liquid CCl_4 , this film increases the affinity of CCl_4 with certain reason, the liquid molecules enter into polymer and cause the swelling of polymer. The reason of their entrance has not yet been evident from the experimental data that has been given. It may, however, be said that some changes are occurred in PVA by irradiation and the value of diffusion constant of CCl_4 in PVA is increased, causing CCl_4 entrance. Then radicals are mainly produced of CCl_4 by radiation, for CCl_4 has the larger G value (70.0)⁴ than that of PVA. This radical reacts upon the PVA molecules, makes intermolecular linkings, and network structure of them.

The diffusion equation for CCl_4 entrance is as follows:

$$r[D(r)]\frac{\partial u}{\partial t} = \frac{dr}{dt} = I, \quad (1)$$

where $D(r)$; the diffusion constant of CCl_4 in PVA polymer, which is the function of total exposed dose of irradiation, r : the total exposed dose of irradiation, I : the dose rate of irradiation, t : the time, $u(x, y, z, t)$: the concentration of CCl_4 in a place (x, y, z) at a time (t) .

The specimens used in Yoshitake's experiments were of 1/100 mm and 3/100 mm films in thickness, and thus equation (1) now becomes one dimensional problem, in which we take x as variable, with the boundary condition of $u(0, r) = u(l, r) = 1$ and the initial condition $u(x, 0) = 0$ for $0 < x < l$ and $u(0, 0) = u(l, 0) = 1$. Here we take the variable r in

stead of t and u is normalize to 1 which is the CCl_4 concentration of corresponding to the maximum swelling, and l is the thickness of specimen.

Equation (1) is solved easily with the resulting formula:

$$u = 1 - \sum_{n=0}^{\infty} \frac{4}{(2n+1)\pi} \sin\left(\frac{2n+1}{l}\pi x\right) \times \exp\left[-\left(\frac{2n+1}{l}\pi\right)^2 \int_0^r \frac{D(r')}{I} dr'\right]. \quad (2)$$

Now we define $U = \int_0^l u dx / \int_0^l dx$, then

$$U = 1 - \sum_{n=0}^{\infty} \frac{8}{\pi^2(2n+1)^2} \times \exp\left[-\left(\frac{2n+1}{l}\pi\right)^2 \int_0^r \frac{D(r')}{I} dr'\right]. \quad (3)$$

Next, let us consider $D(r)$, $D(r)$ must be zero when $r=0$ because CCl_4 scarcely enters into polymer initially, and $D(r)$ may increase linearly with r when r is small, and be constant when r is infinite. Thus we assume the following formula for $D(r)$:

$$D(r) = D_{\infty}(1 - e^{-\alpha r}). \quad (4)$$

We substitute equation (4) to (3), then we acquire the equation:

$$U = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \times \exp\left[-\left(\frac{2n+1}{l}\pi\right)^2 \frac{D_{\infty}}{I} \left(r + \frac{1}{\alpha} e^{-\alpha r} - \frac{1}{\alpha}\right)\right]. \quad (5)$$

As U is the average concentration ratio of liquid molecules in PVA per unit volume to the maximum one, we can compare this value with the data of the increased weight ratio of swollen film to the initial one, that is, $\Delta W/W$. U equals to $\Delta W/\Delta W_m$, where ΔW_m is the maximum of ΔW .

In order to determine the value of D_{∞} and α experimentally from (3) we can obtain the relation:

$$\frac{l(\partial/\partial l)U}{2(\partial/\partial r)U} = \frac{D(r)}{\int_0^r D(r') dr'}, \quad (6)$$

and with (4) we can transform (6) into the following:

$$\frac{l(\partial/\partial l)U}{2(\partial/\partial r)U} = \frac{r}{1 - e^{-\alpha r}} - \frac{1}{\alpha}. \quad (7)$$

The curves of equation (7) are shown Fig. 1. The intercept of the asymptote is to be $1/\alpha$, and the slope for $r=0$ is to be $\alpha/2$, and we

can get α from these relations. This α is substituted to (5) and we can get the unknown parameter D_∞ .

Fig. 1. Relation between $l \frac{\partial U}{\partial l} / 2 \frac{\partial U}{\partial r}$ and r .

● The values which are derived from the data in the neighbourhood of $l=1/100$ mm.

△ The values in the neighbourhood of $l=3/100$ mm.

Next, we consider the relation between irradiation dose and crosslinking number or gel fraction. Let v be the concentration of radicals produced from CCl_4 by radiation such as Cl , CCl_3 etc., δ be the radiation-induced reaction constant of radical production, that is, the yield of radicals per unit dose rate per unit CCl_4 concentration, β be the reaction constant of radical recombination, then the equation for radicals is

$$r(D_v \nabla^2 v) + \delta I u - \beta v^2 = \frac{\partial v}{\partial t} = I \frac{\partial v}{\partial r} \quad (8)$$

Taking into account of $\partial v / \partial t \geq 0$ and $v > 0$, equation (8) becomes

$$0 < v \leq \frac{D_v \nabla^2 + \sqrt{D_v^2 \nabla^4 + 4\beta \delta I u}}{2\beta}$$

One may suppose that D_v is not different so far from D_∞ , which is, as described later, of the order of $10^{-11} \text{ cm}^2 \text{ sec}$. $D_v \nabla^2$ is of the order of $I(\partial/\partial r)$ in equation (1), from experimental data it is of the order of 10^{-6} sec^{-1} , and $\delta I u$ is of the order of $10^{-9} \sim 10^{-8} \text{ sec}^{-1}$ which is obtained from the G value of CCl_4 and its concentration and PVA density. It is very difficult to estimate the order of β , because β concerns the various process, such as the mobility of radical in PVA, the transmis-

sion coefficient of reaction, the activation energy, etc., and can not be measured directly in this case. The smallest β may be obtained from the case of solid polymer phase. We can get the smallest β from the data of paramagnetic resonance⁶, and it seems to be of the order of $10^3 \sim 10^{-1} \text{ sec}^{-1}$. On account of the swollen polymer system in our case, β is supposed to have the larger value than that of solid polymer. And if (8) is stationary in the region of $r=10^6 \sim 10^7 \text{ rad}$, β is the order of $< 10^{10} \text{ sec}^{-1}$. We consider, therefore, three cases when β is of the order of 10^{-1} , 10^8 , and 10^{10} sec^{-1} , which correspond to 10^{-18} , 10^{-13} , $10^{-11} \text{ cm}^3 \text{ sec}^{-1}$ in CGS units respectively. For $\beta=10^{-1} \text{ sec}^{-1}$, we get $0 < v \leq 10^{-4}$ which correspond to the value smaller than 10^{17} radicals cc^{-1} .

The first term of equation (8) is of the order of $10^{-10} \text{ sec}^{-1}$, the second one is of the order of $10^{-9} \sim 10^{-8} \text{ sec}^{-1}$ and the third one is less than the second. Then we ignore the diffusion term in (8) in treating v . In stationary state,

$$v = \sqrt{\frac{\partial I u}{\beta}} \quad (9)$$

and in the other two cases with the numerical calculation by the method of perturbation which is shown in appendix, we obtain v as a function of u and x , namely,

$$v = f(u, x) \quad (9')$$

The crosslinking process is considered in the case of unimolecular, or bimolecular reaction mechanism such as

$$\left. \begin{aligned} \frac{\partial r}{\partial t} &= kv \\ \frac{\partial r}{\partial t} &= kv^2 \end{aligned} \right\} \quad (10)$$

where r is the crosslinking index to the initial molecule of PVA in a place x , k is a constant. But it is said that PVA in the solid state degrade by irradiation⁷ and the gel formation of PVA aqueous solution by irradiation is well explained with a mechanism of endlinking process¹. It is the reason why we must take the bond rupture process of main-chain of PVA into account. Now let r'' be the true crosslinking index which is the average number of crosslinked monomers per molecule, taking the main-chain rupture into account³, then

$$r'' = \frac{r}{1 + P_0 \epsilon r} \quad (11)$$

where P_0 is the number average of number of monomer units for the initial PVA molecules, and ϵ is the probability of the main-chain rupture per monomer per unit dose, equals to $8.7 \times 10^{-11} \text{ rad}^{-1}$ from the data of G value of PVA main-chain rupture, namely, 1.87 . The viscosity average of the degree of polymerization, where exponential factor is 0.62, is 1740 in our case, and so the number average P_0 is 855 with assuming the Poisson distribution for the degree of polymerization.

The measured gel fraction G are related with r'' by the following equation, that is,

$$G = \langle g \rangle_x = \frac{1}{l} \int_0^l g dx \quad (12)$$

where g is the local gel fraction in a place x at a time t , $\langle g \rangle_x$ means x average of g . And

$$\left. \begin{aligned} g &= \frac{1}{2} - \frac{1}{r''} + \sqrt{\frac{1}{4} + \frac{1}{r''}} & \text{for } r'' \geq \frac{1}{2} \\ g &= 0 & \text{for } 0 \leq r'' < \frac{1}{2} \end{aligned} \right\} \quad (13)$$

which is derived from the equation³⁾

$$\begin{aligned} s(1+r''-r''s)^2 &= 1 \\ s &= 1-g \end{aligned}$$

where s is the sol fraction.

Equations (9) and (9') do not involve an unknown parameter, but in (10) k is not known from other data. In order to decide k from the measured gel fraction, one point, that is, the value of r from $G=50\%$ in the specimen of $l=1/100 \text{ mm}$, is used.

With such known parameters, we can calculate G . The line shape of G against r for $l=1/100$, $l=3/100 \text{ mm}$, and the separating space of two curves can be compared with experiments.

§ 3. Comparison with the Experimental Data of Swelling and Gel Fraction

We get α , $1.0 \times 10^{-5} \sim 5.0 \times 10^{-5} \text{ rad}^{-1}$ from Fig. 1, where $\partial u / \partial l$ has been obtained by way of interpolation. Now we take the value of α $2.0 \times 10^{-5} \text{ rad}^{-1}$. Then from the data U and r in Fig. 2, when $l=1/100 \text{ mm}$, we take the value of $D_\infty / l = 1/4 \times 10^{-12} \text{ cm}^2 \text{ rad}^{-1}$. In Fig. 3 we can show U as a function of ρ only, where

$$\rho = D_\infty \left(r + \frac{1}{\alpha} e^{-\alpha r} - \frac{1}{\alpha} \right) / l^2 \quad (14)$$

and the shape of U against ρ agree with each other in the general character. We may, therefore, conclude that U is a formula as shown in (5), and the diffusion process of CCl_4 is regarded to obey generally the equation (1). $D_\infty = 3.13 \times 10^{-11} \text{ cm}^2 \text{ sec}^{-1}$ can be compared with the diffusion constant of gas in rubber which is of the order of $10^{-9} \text{ cm}^2 \text{ sec}^{-1}$, and so be regarded plausible, considering that PVA can permeate gas much less than rubber.

Fig. 2. Relation between weight change ratio and irradiation dose.

● 1/100 mm specimen.
 ▲ 3/100 mm " "

Fig. 3. Relation between U and ρ .

● 1/100 mm.
 ▲ 3/100 mm.

Numerical solutions of (8) with $\beta=1$ and 10^8 sec^{-1} are performed. We see that, when $\beta=10^8 \text{ sec}^{-1}$, v equals almost to that of the stationary state. And that little difference is obtained among four cases, that is, stationary-unimolecular, -bimolecular, nonstationary-unimolecular, and -bimolecular, as shown in Fig. 4, so it is impossible to decide which process is the most proper one to explain. But the

line shapes and the separation of two lines agree well with the experimental data in four cases. While, among these processes in (9), (9'), and (10) the stationary-unimolecular reaction type may be proper. Because, in liquid CCl_4 , β may not be so small, and from G

- stationary and bimolecular type.
- stationary and unimolecular type.
- · - · - unstationary and bimolecular type.
- unstationary and unimolecular type.

Fig. 5. The log-log plot of sol fraction against total dose. (After Yoshitake)

value of CCl_4 and the measured G about 3.2 radicals may produce one crosslink, so crosslinking reaction seems to be of so high efficiency that it is supposed unimolecular. But for deciding the reaction mechanism of crosslinking it is necessary to observe the dose rate dependency of viscosity and gel fraction, and the swelling ratio which is effective when γ'' is large. The relation between $\log(1-G)$ and $\log r$ is shown in Fig. 5 and these curves do not resemble to the Charlesby's ones. The

reason is evident, because in (11) γ is not a linear function of r , and that the crosslinking reaction does not occur homogeneously in every place, so γ'' increases rapidly with r in the neighbourhood of $x \sim 0$, $x \sim l$, and the gel formation takes place early, but late in the neighbourhood of $x \sim l/2$. Consequently it is only the case when l is small ($\sim 1/1000$ mm) and r is large, to be able to compare $\log(1-G)$ with the Charlesby's curve.

§ 4. Changes of the Molecular Weight before Gel Formation

In the above description, we consider the both processes of crosslinking and degradation, and that the ratio of probability $\gamma/\varepsilon p_0$ of crosslinking to that of degradation are not constant as illustrated in Fig. 6. So it is of importance

Fig. 6. The ratio of crosslinking to main-chain rupture is a function of r .

to investigate the behavior of molecular weight before gel formation.

From Saito's equation⁸⁾, we can obtain

$$\begin{aligned} \frac{\partial m(p, r)}{\partial t} + 2pm(p, r)\dot{c}(r) \\ = \dot{c}(r) \int_0^p p'(p-p')m(p', r)m(p-p', r)dp' \end{aligned} \quad (15)$$

and

$$m(p, r) = n(p, r)/N$$

where $n(p, r)$: the number of molecules which have the degree of polymerization p and are exposed to radiation r , $\dot{c}$: the probability of a monomer to form the active centre for crosslinking by unit radiation, which is not a constant but a function of r in our case. In the same manner in reference (8), we can obtain the number average of molecular weight M_n and the weight average of molecular

weight M_w as follows:

$$M_n = M_{n,0} \cdot f_{0,0} / \left(f_{0,0} - \int_0^r \dot{c}(r') dr' \right) \quad (16)$$

where $f_{0,0} = \int_0^\infty m(p, 0) dp$, $M_{n,0}$ is the initial number average of molecular weight, and

$$M_w = M_{w,0} / \left(1 - 2 \int_0^r \dot{c}(r') dr' \cdot f_{2,0} \right) \quad (17)$$

where $f_{2,0} = \int_0^\infty p^2 m(p, 0) dp$, $M_{w,0}$ is the initial weight average of molecular weight.

In order to take the degradation effect into account, we can as well take m involving the effect of degradation for the initial $m(p, 0)$ in calculating $f_{0,0}$ and $f_{2,0}$. By assuming Poisson distribution initially, M_n and M_w become

$$\left. \begin{aligned} M_n &= \frac{M_{n,0}}{1 + \varepsilon p_0 r - p_0 \int_0^r \dot{c}(r') dr'} \\ M_w &= \frac{M_{w,0}}{1 + \varepsilon p_0 r - 4p_0 \int_0^r \dot{c}(r') dr'} \end{aligned} \right\} \quad (18)$$

here

$$2p_0 \dot{c}(r) = \frac{\partial r}{\partial r} \quad \text{and} \quad r = 2p_0 \int_0^r \dot{c}(r') dr'$$

with (9), (9') and (10), we can calculate numerically M_n and M_w against r .

As in every case mentioned in (9), (9') and (10), r is scarcely different from one another when $r \lesssim 3$, we take the simplest case, namely

$$\begin{aligned} r &= 2p_0 \int_0^r \dot{c}(r') dr' = \frac{k\delta I}{\beta} \int_0^r u(r') dr' \\ &= \frac{k\delta I}{\beta} \int_0^r \left\{ 1 - \sum_{n=0}^{\infty} \frac{1}{(2n+1)\pi} \sin \left(\frac{2n+1}{l} \pi x \right) \right. \\ &\quad \times \exp \left[- \left(\frac{2n+1}{l} \pi \right)^2 \right. \\ &\quad \times D_\infty \left(r' + \frac{1}{\alpha} e^{-\alpha r'} - \frac{1}{\alpha} \right) \left. \right] \left. \right\} dr' \quad (19) \end{aligned}$$

For small r , $\int_0^r p_0 \dot{c}(r') dr'$ changes like something in proportion to r^3 in the above case and also in proportion to r^n ($n > 1$) in the other three cases. For large r changes as $r = A - Br$ (A, B are constants) in all cases. Accordingly, when r is small,

$$4p_0 \int_0^r \dot{c}(r') dr' < \varepsilon p_0 r$$

and we obtain

$$\frac{\partial M_n}{\partial r} < 0, \quad \frac{\partial M_w}{\partial r} < 0.$$

When the gel formation occurs, r'' must be $1/2$ in (11), so

$$1 + \varepsilon p_0 r - 4p_0 \int_0^r \dot{c}(r') dr' = 0.$$

Then, M_w must have a minimum as shown in Fig. 7, but M_n has not always a minimum.

Fig. 7. Relation between molecular weight dependence and irradiation dose.

Numerical calculations of $\langle M_n \rangle_x$ and $\langle M_w \rangle_x$ are carried out by the equation:

$$\left. \begin{aligned} \langle M_n \rangle_x &= \frac{1}{l} \int_0^l \frac{M_{n,0} dx}{1 + \varepsilon p_0 r - \frac{1}{2} r(r, x)} \\ \langle M_w \rangle_x &= \frac{1}{l} \int_0^l \frac{M_{w,0} dx}{1 + \varepsilon p_0 r - 2r(r, x)} \end{aligned} \right\} \quad (20)$$

but the averages are not taken into account for M_n and M_w of the following value, that is; $M_n > 4M_{n,0}$ and $M_w > 4M_{w,0}$ respectively, because the measured viscosity is not considered to be detected with these conditions.

It is very difficult to calculate the viscosity average of molecular weight M_v against r (the exponent of viscosity against molecular weight is 0.62 for PVA-H₂O system). But Saito has gotten the viscosity average molecular weight in the analytical form with the constant ratio of crosslinking and degradation. From his formula one can get $M_{1/2}$ with the previous method, that is,

$$M_{1/2} = M_{1/2,0}(1 + p_0 \epsilon r)^{1/2} \int_0^1 \frac{y^{3/2} dy}{(1-y)^{1/2} \left[1 - 2y(y+1) \int_0^r \frac{c(r') dr'}{(1 + p_0 \epsilon r)} \right]^{1/2}}$$

The calculation of $M_{1/2}$ can be easily made by using the table of elliptic integrals¹⁰⁾ and was performed, averaging out with x only for $M_{1/2} \leq 4M_{1/2,0}$. Since the viscosity average of molecular weight M_v is a value between M_w and $M_{1/2}$, the results of calculation agree plausibly with experiments as shown in Fig. 7 which are measured from the aqueous solutions of soluble part of these films.

§ 5. Discussion

The diffusion mechanism in the microscopic sense which causes CCl_4 entrance has not yet been clear, but we may suppose three cases. The first of these is the process that is shown in equation (1), that is, PVA is made by irradiation some chemical changes that occur to increase the diffusion constant of CCl_4 . The chemical changes may be something like bond-rupture or decrystallization.

Second, the permeation of molecule into polymer is regarded to be decided by the solubility for its molecule and the diffusion constant, that is, the permeability constant is represented by the product of the solubility and the diffusion constant. It is also supposed that the entrance of CCl_4 into PVA caused by the change of overall solubility of PVA for CCl_4 . If so, the equation that determine $u(x, r)$ is the following form, i.e.

$$D \nabla^2 u = I \frac{\partial u}{\partial r} \quad (22)$$

with the initial and the boundary conditions:

$$u(x, 0) = 0$$

$$u(0, r) = u(l, r) = 1 - e^{-ar}$$

where the boundary condition $1 - e^{-ar}$ is the overall solubility that changes in this case with r and D is constant.

We can solve equation (22) by the method of Duhamel¹¹⁾, with the resulting formula

$$\left. \begin{aligned} u &= \sum_{n=0}^{\infty} \frac{4}{(2n+1)\pi} \sin \left(\frac{2n+1}{l} \pi x \right) \\ &\times \left\{ 1 - e^{-Br} - \frac{B}{B-a} (e^{-ar} - e^{-Br}) \right\} \\ B &= \frac{D}{I} \left(\frac{2n+1}{l} \pi \right)^2 \end{aligned} \right\} \quad (23)$$

and

$$U = \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} \left\{ 1 - e^{-Br} - \frac{B}{B-a} (e^{-ar} - e^{-Br}) \right\}, \quad (24)$$

on the other hand equation (2) becomes

$$u = \sum_{n=0}^{\infty} \frac{4}{(2n+1)\pi} \sin \left(\frac{2n+1}{l} \pi x \right) \times \{ 1 - e^{-Br} - (\exp(-(2n+1)^2 \rho) - e^{-Br}) \}. \quad (25)$$

Comparing (23) with (25), we can see that both equations resemble to each other in x and r dependency, and choosing the favourable values of D and a , we can make u in (23) agree with experiment. In fact, u in (23) agrees with experiment in every case of $l=1/100$ and $l=3/100$ mm with the values of $D=D_{\infty}$ and $a \cong (1/3) \cdot D_{\infty}/I(\pi/l)^2$.

Third, HCl or PVA chloride, for instance, are produced in PVA by irradiation after reacting CCl_4 or Cl_2 to PVA molecule, and more CCl_4 enters into the solid polymer as the results of inducing of HCl or PVA chloride. The presence of HCl or PVA chloride may determine the local solubility of PVA for CCl_4 , and so u is a function of HCl concentration or chloride contents in PVA molecule. According to this view, the diffusion equation is as follows:

$$\nabla [D \nabla u + \text{grad } V(u)] = \frac{\partial u}{\partial r} \quad (26)$$

where $V(u)$ is a potential for CCl_4 in PVA. Equation (26) becomes

$$\nabla \left[\left(D + \frac{\partial V(u)}{\partial u} \right) \nabla u \right] = I \frac{\partial u}{\partial r} \quad (27)$$

In general character, V must be infinite or very large value for $u=0$, because none of CCl_4 entered into PVA, and must have minimum for $u=1$, because when $u=1$ and force is not act on CCl_4 in PVA. $D(r)$ in (1) may regard as corresponding to $\langle D + \partial V / \partial u \rangle_x$ in (27), here $\langle D + \partial V / \partial u \rangle_x$ means the x average of $D + \partial V / \partial u$. More generally we may consider the equation such as

$$\nabla^2 u + \nabla^2 V(x, y, z, r) = I \frac{\partial u}{\partial r}$$

And in the case of one dimensional problem by means of Laplace transformation of r , we

can obtain the potential form of $V(x, r)$ from the data of l and r dependency of experimental U . In order to study this process more completely, one expects the measuring data of more various shapes and thickness of specimens and of its temperature dependency.

One may anxious to use (11) and to take m involving the effect of degradation, for the initial $m(p, 0)$ in calculating $f_{0,0}$ and $f_{2,0}$ in (16) and (17) in spite of non-constant ratio of crosslinking and main-chain rupture. Nevertheless, it is proper, because in Charlesby's or Saito's theory, nothing like the velocity of crosslinking or degradation, or the sequences of these processes is taken into account, and the matter is treated as it is static.

In above we have considered crosslinking only to explain the forming of gel, but it is possible to suppose to cause the gel formation as a result of endlinking process. And it is difficult to conclude which process, crosslinking or endlinking, is more proper without other experimental results. Anyway, it is known that, no sooner the chain rupture has occurred by 2/3 per initial molecule, than the gel formation has begun to appear when the radicals of ruptured end is most effectively used¹²⁾. Only 0.5 bond per number average molecule is ruptured directly for 3×10^6 rad which correspond to the dose of 50% gel fraction of 1/100 mm specimen. According to the high efficiency of gel formation and to the effect of specimen's thickness, the bond rupture for endlinking must be caused by the influence of radicals from CCl_4 or HCl , if the endlinking process be the main process. But it does not seem natural to suppose the process of the main-chain rupture by the external radicals, for its reaction must be complicated one.

Acknowledgement

The author is much indebted to Mr. T. Yoshitake for his kind offer of experimental data. And he wishes to express his grateful thanks to Prof. A. Amemiya and Dr. K. Shinohara for their helpful advice from mathematical and experimental aspects, and to Prof. O. Saito and Mr. M. Inokuti for their valuable remarks and suggestions. He also thanks to other members of the Group for the Study of Irradiated Polymers in Tokyo, who gave the usefull discussions.

Appendix

In order to solve equation (8) neglecting the diffusion term, with non-stationary state, the method of perturbation is used as follows. As u is a slowly varying function of r , u can be expanded with r 's power series, that is,

$$u = u_0 + u_1(r - r_i) + u_2(r - r_i)^2 + \dots \quad (\text{A1})$$

And we set

$$v = v_0 + v_1 + v_2 + \dots$$

that is, the solution of zeroth order, first order and second order approximation, etc.

One can easily obtain v_0 , namely,

$$v_0 = \sqrt{\frac{I\delta u_0}{\beta}} \tanh \left\{ \sqrt{\frac{\beta}{I}} [(r - r_i) + r_i'] \right\}, \quad (\text{A2})$$

where r_i' is determined with the condition $v_0 = v(r_i')$ for $r = r_i'$. And v_1 becomes

$$v_1 = \exp \left(-2 \int_{r_i}^r \frac{\beta}{I} v_0 dr' \right) \times \left[\int_{r_i}^r \delta u_1(r' - r_i) \cdot \exp \left(2 \int_{r_i}^{r'} \frac{\beta}{I} v_0 dr'' \right) dr' \right] \quad (\text{A3})$$

with assuming $v_1 v_0 \gg v_1^2$.

But when $r_0 = 0$ the expanded form of u do involve zeroth power of r , then we must solve (8) by some different method. In this case, in (A1) $u_0 = 0$ and $v_0 = 0$, equation for v_1 is

$$\delta I u_1 r - \beta v_1^2 = I \frac{dv_1}{dr}. \quad (\text{A4})$$

When we set

$$\frac{\beta}{I} v_1 = \frac{1}{\eta} \frac{d\eta}{dr}$$

and

$$r = \frac{3}{2} \xi^{2/3} \quad \eta = \xi^{1/3} \omega. \quad (\text{A5})$$

Equation (A4) becomes

$$\frac{d^2 \omega}{d\xi^2} + \frac{1}{\xi} \frac{d\omega}{d\xi} - \frac{1}{9} \frac{\omega}{\xi^2} - \delta u_1 \frac{\beta}{I} \omega = 0.$$

And we can solve easily with the resulting formula,

$$\omega = A J_{1/3} \left\{ \sqrt{-\delta u_1 \frac{\beta}{I} \xi} \right\} + B J_{-1/3} \left\{ \sqrt{-\delta u_1 \frac{\beta}{I} \xi} \right\} \quad (\text{A6})$$

where A and B are constant.

Considering that r is small, and

$$v_1 = \frac{\delta I u_1}{4\beta} r^2. \quad (\text{A7})$$

Next, we divide r axis into n parts, and

denote r and u as follows

$$r_0, r_1, r_2, \dots, r_i, \dots, r_n$$

$$r_{i+1} - r_i = \Delta r$$

$$u(r_0) = u(0) = 0$$

$$u(r_1) = u(1), u(r_2) = u(2), \dots, u(r_i) = u(i), \text{ etc.}$$

and

$$u_1(i) = \frac{u(i+1) - u(i)}{\Delta r}.$$

Considering that $(r - r_i)$ is small and $v \ll 1$ with above expression we can obtain $v(i)$ from the value of $v(i-1)$ using the successive approximation, namely,

$$\left. \begin{aligned} v(i) = & v(i-1) + \left[2\sqrt{\delta u(i-1)} \left(1 + \frac{\beta v(i-1)^2}{I \delta u(i-1)} \right) \right. \\ & + \frac{\delta}{2} (u(i) - u(i-1)) \Big] \Delta r \\ & - 4 \frac{\beta}{I} \left[\left(1 + \frac{\beta v(i-1)^2}{I \delta u(i-1)} \right) v(i-1) \right] \Delta r^2 \\ & \qquad \qquad \qquad \text{for } i \neq 1 \\ \text{and} \\ v(1) = & \frac{\delta I u(1)}{4\beta} \cdot \Delta r \qquad \qquad \text{for } i = 1 \end{aligned} \right\} \quad (A8)$$

The Study of the Transition Phenomena of Chain Polymers by the Photoelastic Method

By Motozo KANEKO

Department of Physics, Faculty of Science,
Hokkaido University

(Received July 5, 1958)

In the present work, it is reported that the glass transition phenomena of chain polymers can be studied by observing the temperature dependency of the photoelasticity of the materials, and the transition temperature determined using this method agrees with the second order transition point by the specific volume method for P.V.C., but for polystyrene it is a little higher and rather near to the softening point by the dynamical elastic method.

§ 1. Introduction

The glass transition phenomena of chain polymers have been studied by a few methods of measurement. These phenomena are also studied by means of the temperature depend-

ency of photoelasticity.^{1),2)} This photoelastic method appears to be a kind of elastic method, but it is applicable to the measurement in a softening state as it is not so strongly interrupted by the plastic flow as an ordinary

elastic method. And also it is profitable in observing of the existence of a rubber-like state. In the present work the transition point of chain polymers, especially of polystyrene, and the existence of a rubber-like state above that point are investigated by this method.

§ 2. Experimental Method

To maintain the plastic flow of specimens as small as possible, it is desirable that the tension applied to specimens is small. For that reason Szivessy-Dierksmann's compensation method³⁾ which is applicable to the measurement of weak birefringence was used. The compensation plates were made of mica and the birefringences of the plates were 0.148 (N_D) for the weak birefringence and 1.45 (N_D) for usual one. As the birefringence as weak as about 0.001 radian could be observed by this method, the measurement could be done under small tension whose order is about 100 g/cm².

The films of commercial polystyrene ($\bar{M}_v = 270,000$) and polyvinyl chloride (P.V.C.) ($\bar{M}_v = 47,000$) were used as specimens. These films were cast from solutions of the materials, chlorobenzene solution for polystyrene and nitrobenzene solution for P.V.C. Then they were carefully dried. From a part with uniform thickness of these films, strips were cut out, each with a size of 1.5 cm in width and 2.3 cm in length. Their thickness was 0.05~0.07 mm for polystyrene and 0.25 mm for P.V.C.

These strips were hung perpendicularly in the center of a little furnace with two windows through which the birefringence was observed. The lower end of the strip was tied by the wire, a part of which was put out of the furnace. The weight was applied on the lower end of this wire for the purpose of changing the tensile load at the outside of the furnace. And at the same time the elongation of the specimens was observed by measuring the displacement of the end of this wire by a microscope. The temperature of the furnace was raised at the rate of about 0.5°C/min during observation by controlling the electric current. The temperature of strips was read by the thermometer which was inserted in the center of the furnace. In all measurement, N_D was used as the source of light.

In order to put the strips under the uniform tension, the both ends of the strip were clipped by the two small metal plates.

§ 3. Results and Discussion

The results for polystyrene are shown Fig. 1. Below about 80°C the birefringence is seldom observed. Passing through about 80°C, the birefringence begins to appear slightly, but the value is still very small. At tempera-

Fig. 1. The temperature dependency of the birefringence of Polystyrene. (The sign of the birefringence is negative)

tures from 100°C to 120°C the absolute value of the birefringence suddenly increases. Above 120°C it appears that the value slightly decreases with increasing temperature. The first region in which the birefringence does not appear may be in an amorphous solid state. The birefringence in this region is believed to be too weak to be observed under such small tension as applied in this experiment. It is likely that the second region where the birefringence begins to appear and shows a sudden increase is in a transition state. Also recognized in this region is the elongation of the specimens which does not appear in the first region. For example, in case of the curve for the tension of 90 g/cm² in Fig. 1, the elongation of a specimen at

about 120°C becomes about 1%; above this temperature the elongation increases and the absolute value of the birefringence decreases with increasing the temperature; and the elongation at about 140°C is about 2% against the length at 120°C. If compensation is made for the value of the birefringence on the assumption that the volume is kept constant, as is the case with the rubber-like material, the absolute value of the birefringence should increase about 1% with the increase in tension of about 2% and the decrease in thickness of about 1%. However, the observed value of the birefringence at 140°C indicates a decrease of about 20% against the value measured at 120°C. Therefore, it seems reasonable to assume that in the region where the absolute value of the birefringence decreases the specimen is in a rubber-like state and its birefringence is proportional to the reciprocal of absolute temperature, as known from a theory for the birefringence of the rubber-like material⁽⁴⁾. Likewise it applies to all the curves for different tensions. Though the elongation becomes larger with the increase in tension, such a large decrease in the absolute value of the birefringence as measured is unexplainable by considering the compensation for the elongation alone. It is also interesting to note that the rate of the decrease in that value becomes larger with the increase in tension. This can likewise be expected from the theory for the birefringence of the rubber-like material⁽⁴⁾. If these facts are considered, it is likely that the third region where the absolute value of the birefringence decreases as shown in Fig. 1 is in a rubber-like state. As the temperature is raised higher, other regions appear where the elongation increases rapidly and the absolute value of the birefringence shows again a tendency for increase,^(1),2) although in this figure the regions showing the increase in that value are not plotted.

When the tension is decreased at 140°C, both the elongation and the absolute value of the birefringence are slowly decreasing. But the former never returns to the latter. This indicates that the plastic flow is included in this elongation.

If the first region were in a solid-like state and the third region were in a rubber-like state, according to the above discussion, the

second region, that is the transition region, would be the one where the materials change to a rubber like state from a solid like state. In the first place of this region the materials may rapidly change to a rubber like stage and the observed value of the birefringence becomes larger but in the final state the rate of the increase of that value may be lowered by the opposite effect of the part changed to the rubber like stage. Then here it is assumed that the glass transition point is the inflexion point of the second region of the curve in Fig. 1. The transition point obtained by the above assumption are plotted against tensions in Fig. 2. From this figure it is re-

Fig. 2. The relationship between the transition points and the tensions.

vealed that the transition point shifts slightly to the lower temperature side with the increase in tension, as the case of Nielsen et al⁽⁵⁾ and that, when tension is extrapolated to zero, the transition temperature approximates 115°C. This value is fairly higher than the second order transition point estimated by means of specific volume^(6),7,8) or specific heat⁽⁹⁾. However, this one nearly agrees with the so-called softening point obtained by the dynamical elastic measurement⁽¹⁰⁾.

The temperature at which the birefringence begins to appear was not discussed because of the accuracy of the present work, but it is likely that this temperature also slightly depended on the tensile load.

*Fig. 3 shows the results for P.V.C. In this case the shape of the curve is also the same as that for polystyrene. In this figure the region of plastic flow is also shown. In the case for P.V.C. the transition point has likewise the tendency of decreasing with increasing tension. The transition points estimated from Fig. 2 are 74°C for 100 g/cm² tension

and 70°C for 200 g/cm² tension. This value is near the so-called second order transition point obtained by means of specific volume⁶⁾.

It has been reported that the rubber-like stage does not appear for polystyrene¹¹⁾, but the foregoing results obtained by our experiment suggest the existence of a rubber-like

styrene reported in the past work is a little lower than in the present work¹⁾. It is believed that the difference was caused by the insufficient drying of samples in the past measurement which permitted solvent remaining in the samples to act as plasticizer²⁾.

stage for polystyrene. This may be attributable to the fact that, as the amount of tension was not sufficiently large in our experiment, effects by the secondary cross-linkage due to entanglement, and so forth, were working. It is likely that the effectiveness of the secondary cross-linkage was a cause of the lowering of the transition point with the increasing tension.

The value of the transition point for poly-

Paramagnetic Relaxation of Copper Tutton Salt

Yosuke NAGAOKA

Department of Physics, University of Tokyo, Tokyo

(Received July 17, 1958)

The spin-lattice relaxation time of Cu-Tutton salt is calculated basing on the Van Vleck theory. At liquid helium temperatures, calculated relaxation time shows a remarkable anisotropy, which arises from the nature of orbital states of Cu^{2+} in the crystalline field. Its order of magnitude is too large compared with the value 2×10^{-4} sec. measured by Townes et al.. At liquid air temperatures, however, it is in fairly good agreement with experimental data if a reasonable value is assumed for the separation of the first excited orbital state from the ground state.

§ 1. Introduction

The spin-lattice relaxation time of paramagnetic salts was calculated by Van Vleck¹⁾⁻³⁾ for Cr- and Ti-alum. He considered the mechanism that the lattice vibrations modulate the spin-orbit coupling and reverse spins through it. The results of his calculation were in fairly good agreement with experimental data at liquid air temperatures in the order of magnitude of the relaxation time and its dependence on magnetic field and temperature. At liquid helium temperatures, however, there remains a big discrepancy between theory and experiments.⁴⁾

At present this discrepancy is attributed to the fact that the bottleneck of the relaxation is not the energy transfer between the spin system and the lattice but between the lattice and the helium bath, and that the relaxation time observed in usual experiments is the lattice-bath (not spin-lattice) one. Townes and co-workers⁵⁾ have presented experimental evidence indicating this. They have observed also the time constant which they think is the true spin-lattice relaxation time. It is about 2×10^{-4} sec. for Cu-Tutton salt.

However Bloembergen⁶⁾ has recently pointed out that such a strong coupling between the spins and the lattice is incompatible with the successful operation of three-level steady-state masers in some salts. If his objection is right, the relaxation time of Cu-Tutton salt may also be longer than that measured by Townes et al..

In the present paper we shall calculate the spin-lattice relaxation time of Cu-Tutton salt on the basis of the Van Vleck theory. In

Tutton salts each divalent cation is surrounded by a slightly distorted octahedron of six water molecules just like a trivalent cation in alums. In the case of Cu^{2+} ions, however, the orbital states in the crystalline field have a different property from Ti^{3+} and Cr^{3+} ; i.e. the lower states Γ_3 separated from the upper by the cubic field are degenerate (see Fig. 1) but are non-magnetic unlike Ti^{3+} . Then we should take into account also the upper states Γ_5 in the perturbational calculation. Because of this the relaxation time of Cu-Tutton salt shows a new property which is not seen in the cases of Ti^{3+} and Cr^{3+} ; i.e. a remarkable anisotropy as to the direction of an external magnetic field.

The calculation is rather straightforward and is done nearly in a parallel way to the

Fig. 1. Splitting of the orbital states of Cu^{2+} by the crystalline field.

cases of Ti- and Cr-alum. In the following sections we show only essential points of the calculation and the main results.

§ 2. Orbital States in the Crystalline Field

The ground state of the free Cu^{2+} ion is $3d^9 {}^2D$. In the crystalline field of Tutton salts, which has a rhombic symmetry, it splits as shown in Fig. 1. If we label the split states as 1, 2, 3, 4 and 5 from the bottom, their wave functions are given as follows:

$$\left. \begin{aligned} \psi_1 &= \frac{1}{\sqrt{2}}(\varphi_2 + \varphi_{-2}) + c\varphi_0 \\ \psi_2 &= \varphi_0 - c \frac{1}{\sqrt{2}}(\varphi_2 + \varphi_{-2}) \\ \psi_3 &= \frac{1}{\sqrt{2}i}(\varphi_2 - \varphi_{-2}) \\ \psi_4 &= \frac{1}{\sqrt{2}i}(\varphi_1 + \varphi_{-1}) \\ \psi_5 &= \frac{1}{\sqrt{2}}(\varphi_1 - \varphi_{-1}) \end{aligned} \right\} \quad (1)$$

Here φ_M 's are the eigenfunctions of the component of the orbital angular momentum along the approximate tetragonal axis, and c is a constant determined by the ratio of rhombic component to tetragonal one of the crystalline field. We assume $|c| \ll 1$.

The values of g -factor of Cu-K-Tutton salt measured at 90°K are⁷⁾

$$g_x = 2.14, \quad g_y = 2.04, \quad g_z = 2.36. \quad (2)$$

Making use of these values, we can estimate magnitudes of level separations and c . If we neglect the separation among the states 3, 4 and 5 of Γ_6 , the separation Δ between 1 and Γ_6 and c are obtained as

$$\Delta = 15500 \text{ cm}^{-1}, \quad c = 0.15, \quad (3)$$

taking the spin-orbit interaction constant $\lambda = -710 \text{ cm}^{-1}$.⁸⁾ The separation Δ' between 1 and 2 is not known because it has no effect on g -factor.

§ 3. Calculation of Direct Processes

The original Hamiltonian is given as follows:

$$\mathcal{H} = \mathcal{H}_o + \mathcal{H}_l + \mathcal{H}_{zs} + \mathcal{H}_{zo} + \mathcal{H}_{so} + \mathcal{H}_{ol}. \quad (4)$$

Here $\mathcal{H}_o$ is the Hamiltonian for the orbital motion of d -electrons of Cu^{2+} , $\mathcal{H}_l$ that for the lattice vibrations, $\mathcal{H}_{zs} = 2\mu_B \mathbf{H} \cdot \mathbf{S}$ and $\mathcal{H}_{zo} = \mu_B \mathbf{H} \cdot \mathbf{L}$ (μ_B = the Bohr magneton) re-

spectively the spin and orbital part of the Zeeman energy, $\mathcal{H}_{so}$ the spin-orbit interaction and $\mathcal{H}_{ol}$ the orbit-lattice interaction. The spin-spin interaction is neglected assuming that the sample is magnetically dilute. Now we take $\mathcal{H}_o + \mathcal{H}_l + \mathcal{H}_{zs}$ as the unperturbed Hamiltonian and $\mathcal{H}_{zo} + \mathcal{H}_{so} + \mathcal{H}_{ol}$ as the perturbation, and carry out a perturbational calculation of higher order. By eliminating the orbital motion we obtain the effective Hamiltonian $\mathcal{H}_{sl}$ which represents the spin-lattice interaction. Then (4) is effectively reduced to

$$\mathcal{H}_{eff} = \mathcal{H}_{zs} + \mathcal{H}_l + \mathcal{H}_{sl}. \quad (5)$$

In connection with $\mathcal{H}_{ol}$, we have only to consider the vibrational modes of the complex $\text{Cu}^{2+} \cdot 6\text{H}_2\text{O}$ which are even with respect to inversion when we calculate direct processes, as Van Vleck has pointed out. Neglecting the distortion of $6\text{H}_2\text{O}$ from an octahedron, even modes are Q_1 (totally symmetric vibration, representation: Γ_{1g}); Q_2, Q_3 (Γ_{3g}); Q_4, Q_5, Q_6 (Γ_{5g}); Q_{19}, Q_{20}, Q_{21} (rotational motion, Γ_{4g})¹⁾. Now we should take into account not only $Q_2 \sim Q_6$ as in the cases of Ti^{3+} and Cr^{3+} , but also Q_1 and Q_{19}, Q_{20}, Q_{21} , for the orbital states have the translational properties of Γ_3 and Γ_6 and their products are

$$\begin{aligned} [\Gamma_3^2]^* &= \Gamma_{1g} + \Gamma_{3g} \\ [\Gamma_6^2] &= \Gamma_{1g} + \Gamma_{3g} + \Gamma_{5g} \\ \Gamma_3 \times \Gamma_6 &= \Gamma_{4g} + \Gamma_{5g}. \end{aligned} \quad (6)$$

Then each mode has non-vanishing matrix elements only between the following orbital states.

$$\begin{aligned} Q_1 &: \Gamma_3 - \Gamma_3, \Gamma_6 - \Gamma_6. \text{ (diagonal)} \\ Q_2, Q_3 &: \Gamma_3 - \Gamma_3, \Gamma_6 - \Gamma_6. \\ Q_4, Q_5, Q_6 &: \Gamma_6 - \Gamma_6, \Gamma_3 - \Gamma_6. \\ Q_{19}, Q_{20}, Q_{21} &: \Gamma_3 - \Gamma_6. \end{aligned}$$

Taking a point dipole model for the crystalline field, we explicitly obtain $\mathcal{H}_{ol}$ linear in these Q 's.

In $\mathcal{H}_{sl}$ appear two kinds of terms, *adiabatic* and *non-adiabatic* terms.

(1) Adiabatic terms.

These terms are obtained by the so-called adiabatic approximation, i.e. by carrying out the perturbational calculation leaving $\mathbf{S}$ and $\mathbf{Q}$ as operators. So in order to reverse spin,

* $[\Gamma^2]$ denotes the representation of the symmetric product of Γ with itself.

according to Kramers' theorem, it requires the magnetic field and hence the third order perturbation including $\mathcal{H}_{zo}$ as well as $\mathcal{H}_{so}$ and $\mathcal{H}_{ol}$. In other words these are the effect of the lattice vibrations on g -factor in the spin Hamiltonian.

We remark here that there are two kinds of terms different in the order of magnitude.

(a) Terms, the denominator of which is Δ^2 : e.g.

$$(1|\mathcal{H}_{ol}|3)(3|\mathcal{H}_{so}|5)(5|\mathcal{H}_{zo}|1)/\Delta^2.$$

(b) Terms, the denominator of which is $\Delta\Delta'$: e.g.

$$(1|\mathcal{H}_{ol}|2)(2|\mathcal{H}_{so}|5)(5|\mathcal{H}_{zo}|1)/\Delta\Delta'.^*$$

Terms (b) are larger than (a) by the factor Δ/Δ' . Because 1 and 2 are connected neither by $\mathcal{H}_{so}$ nor $\mathcal{H}_{zo}$, in terms (b) $\mathcal{H}_{so}$ and $\mathcal{H}_{zo}$ appear always in such a form as

$$(2|\mathcal{H}_{so}|\Gamma_5)(\Gamma_5|\mathcal{H}_{zo}|1) = \lambda\mu_B S \cdot (2|L|\Gamma_5)(\Gamma_5|L|1) \cdot H. \quad (7)$$

As one can see easily, the factor $(2|L|\Gamma_5)(\Gamma_5|L|1)$ does not vanish only when LL is equal to L_xL_x , L_yL_y or L_zL_z , where x , y and z correspond to the axes of the crystalline field. As a result terms (b) are always proportional to either S_xH_x , S_yH_y or S_zH_z .

(2) Non-adiabatic terms.

When we calculate adiabatic terms, contributions of $\mathcal{H}_i$ and $\mathcal{H}_{zs}$ to the energy difference appearing in the denominator is neglected, so we obtain none from the second order perturbation. If we do not neglect them, however, we get the spin-lattice interaction from the second order perturbation of $\mathcal{H}_{so}$ and $\mathcal{H}_{ol}$ too. These terms are of the same order as (a) of adiabatic terms.

In order to proceed to the numerical evaluation of the relaxation time of direct processes, it is necessary to know the values of a few constants. We use (2) and the following values:

$$e\mu\langle r^4 \rangle R^{-6} = 1900 \text{ cm}^{-1}$$

$$e\mu\langle r^2 \rangle R^{-4} = 5200 \text{ cm}^{-1}$$

$$\text{density: } d = 2 \text{ g/cm}^3 \quad (8)$$

$$\text{sound velocity: } v = 2.3 \times 10^5 \text{ cm/sec}$$

$$\Delta/\Delta' \simeq 2 \sim 10.$$

Here $-e$ is the electron charge, μ the dipole moment of a water molecule, R the distance between Cu^{2+} and H_2O , $\langle r^2 \rangle$ and $\langle r^4 \rangle$ respec-

tively the mean square and mean forth power radius of the d -electron orbit. The value of $e\mu\langle r^4 \rangle R^{-6}$ can be evaluated directly from that of Δ under the assumption of a point dipole model of the crystalline field. $e\mu\langle r^2 \rangle R^{-4}$ is obtained from $e\mu\langle r^4 \rangle R^{-6}$ assuming that the wave function of d -electrons is hydrogen-like and further $\langle r^2 \rangle = 0.9 \times 10^{-16} \text{ cm}^{-1}$ ($R = 2 \text{ \AA}$). Unfortunately no specific heat data of the lattice vibration of Tutton salts can be found, so we take the value of sound velocity used by Van Vleck for alums. We cannot estimate Δ' from experimental data but the above value of Δ/Δ' may be plausible.

Finally the relaxation time τ_{sl} of direct processes is as follows:

$$\text{if } kT \gg \mu_B H,$$

$$\tau_{sl} = 0.78 \times 10^{16} F^{-1} \cdot H^{-4} T^{-1}, \quad (9)$$

$$\text{and if } kT \ll \mu_B H,$$

$$\tau_{sl} = 1.1 \times 10^{20} F^{-1} \cdot H^{-5}. \quad (9')$$

$$F = \alpha_1 + \alpha_2 n^2 + \alpha_3 n^2(n^2 - 1) + \alpha_4(1 - l^4 - m^4 - n^4) + \beta_1(m^2 - l^2) + \beta_2 n^2(m^2 - l^2). \quad (10)$$

Here H is the applied magnetic field in oersteds, T the temperature in $^\circ\text{K}$, (l, m, n) the directional cosine of H and

$$\left. \begin{aligned} \alpha_1 &= 0.015 \\ \alpha_2 &= 1.3 \\ \alpha_3 &= 2.8 \left(\frac{\Delta}{\Delta'} \right)^2 + 0.5 \left(\frac{\Delta}{\Delta'} \right) + 0.4 \\ \alpha_4 &= 1.9 \left(\frac{\Delta}{\Delta'} \right)^2 + 0.3 \left(\frac{\Delta}{\Delta'} \right) \\ \beta_1 &= 0.013 \\ \beta_2 &= 0.28 \left(\frac{\Delta}{\Delta'} \right)^2 + 0.10 \left(\frac{\Delta}{\Delta'} \right). \end{aligned} \right\} \quad (11)$$

In Fig. 2 we show the dependence of F (proportional to τ_{sl}^{-1}) on the direction of the magnetic field in a few planes. An interesting fact is that τ_{sl} becomes extremely long when the magnetic field is parallel to a principal axis of the crystalline field. It is much shorter in other cases. This anisotropy is the more emphasized, the larger Δ/Δ' is.

Such a remarkable anisotropy arises from the fact that in $\mathcal{H}_{sl}$ there are terms (b) larger than others by a factor Δ/Δ' . These terms are proportional to H_xS_x , H_yS_y or H_zS_z , and therefore unable to reverse spins and to have any effect on the relaxation time if the magnetic field is parallel to a crystalline field axis. It should be noticed here that

* The modes Q_2 and Q_3 connect 1 with 2.

Table I. τ_{sl} of direct processes (sec.)

$H(\phi)$	$T(^{\circ}\text{K})$	Direction of H				
		(100)	(010)	(001)	(110)	
3000	4	1.2×10^4	8.6×10^3	1.9×10	5.9*	$2.5 \times 10^{-1**}$
	1	4.8×10^4	3.4×10^3	7.4×10	2.3×10	1.0
10000	4	9.8×10	7.0	1.5×10^{-1}	4.8×10^{-1}	2.1×10^{-3}
	1	3.9×10^3	2.8×10	6.0×10^{-1}	1.9×10^{-1}	8.2×10^{-3}

* $\Delta/\Delta' = 2$,** $\Delta/\Delta' = 10$.Values at $H=10000\phi$, $T=1^{\circ}\text{K}$ are obtained by means of (9), although $kT \approx \mu_B H$ in this case.Fig. 2. Dependence of the value of $F/F_{\max}$ ($\approx F/F_{(110)}$) on the magnetic field direction.(a) x - z plane.(b) x - y plane.(c) z -(110) plane.

Vleck theory; i.e. the crystalline field approximation, its point dipole model, the Debye approximation of the lattice vibrations and so on.

We show numerical results in Table I. The value of the spin-lattice relaxation time of Cu-NH_4 -Tutton salt measured by Townes et al.⁵⁾ is of the order 2×10^{-4} sec. at the frequency 9000 Mc ($H \approx 3000\phi$) and the temperature $1.3 \sim 4^{\circ}\text{K}$. The values calculated here are too large compared with this experimental result. Townes et al.⁵⁾ have also found the anisotropy of the relaxation time in connection with the phenomenon of the asymmetry of the cross saturation. But as the direction of the magnetic field is not shown in the paper, it is not clear whether their observation can be explained by our result.

§ 4. Calculation of Raman Processes

We now proceed to the calculation of Raman processes. The most important contributions are from non-adiabatic terms obtained by means of the third order perturbation $\mathcal{H}_{ol}^2 \mathcal{H}_{so}$ ($\mathcal{H}_{ol}$: linear in Q 's) in which one of the intermediate state is 2; e.g.

$$\frac{(1, n_k | \mathcal{H}_{ol}^2 | 2, n_k + 1)(2 + | \mathcal{H}_{so} | 4 -) \times (4, n_{k'} | \mathcal{H}_{ol} | 1, n_{k'} - 1)}{(-\Delta' - \hbar\omega_k)(-\Delta - \hbar\omega_{k'})}$$

Here n_k represents the number of phonons with wave number k and frequency ω_k . We calculate only such

such anisotropy is, at least qualitatively, independent of approximations taken in the Van terms.

Neglecting effects of the rhombic component of the crystalline field ($c=0$) for simplicity, final results are as follows:

$$\tau_{sl} = \tau_0 \frac{b + CH^2}{b + pCH^2} \quad p=0.5 \quad (12)$$

$$\tau_0 = \rho(1 + 0.23 n^2)^{-1}, \quad (13)$$

where ρ is a constant dependent on temperature and n is the cosine of the angle between the magnetic field and the tetragonal axis. We do not neglect the spin-spin interaction here. As Eq. (13) shows, τ_{sl} of Raman processes has not so remarkable anisotropy as that of direct processes. The numerical values of ρ are shown in Table II. In the calculation of ρ at liquid air temperatures the Debye temperature was assumed to be 330°K.³⁾

Table II. ρ of (13). (sec.)

$T(^{\circ}\text{K})$				
Δ/Δ'	1	4	77	90
2	1.0×10^7	3.8×10	1.9×10^{-6}	1.0×10^{-6}
3	2.6×10^6	9.9	4.7×10^{-7}	2.6×10^{-7}
10	3.7×10^4	1.4×10^{-1}	6.8×10^{-9}	3.7×10^{-9}

Comparing these values of Raman processes with those of direct processes calculated in § 3, we see that even at $T=4^{\circ}\text{K}$ Raman processes are more effective than direct processes if the magnetic field is not so strong and is parallel to a crystalline field axis. As a result the anisotropy at helium temperatures will be smaller than expected from the calculation of direct processes.

In the liquid air region the calculated values are in good agreement with experimental results if we take $\Delta/\Delta'=3$. We show in Table III the values averaged over the direction of the magnetic field with experimental results

of Cu-NH₄-Tutton salt.⁹⁾ Our calculations are so rough that we cannot regard this agreement as a proof that $\Delta' = \Delta/3 = 5000 \text{ cm}^{-1}$. However it may well be said at least that

Table III. τ_{sl} at liquid air temperatures. (sec.)
Experimental results are for Cu-NH₄-Tutton salt.

T		$\tau_0 \cdot 10^6$	$\tau_{\infty} \cdot 10^6$	p
77°K	calc.	0.43	0.87	0.5
	exp.	0.35	0.7	0.5
90°K	calc.	0.24	0.48	0.5
	exp.	0.24	0.4	0.6

the Van Vleck theory agrees with experiments at liquid air temperatures for Cu-Tutton salts too.

The author wishes to express his sincere thanks to Professor R. Kubo for his kind guidance, and to Dr. T. Moriya and to the members of Kubo Laboratory for their helpful discussions.

Spin Quenching and Magnetic Resonance

By Tôru MORIYA

Department of Physics, Tokyo Metropolitan University

and Yukio OBATA

Department of Physics, University of Tokyo

(Received August 2, 1958)

The effect of the magnetic ions of those paramagnetic salts whose spin degeneracy is completely lifted by the combined action of the spin-orbit coupling and the crystalline electric field, on the magnetic resonance of nuclear spins and electronic spins of other kind of ions such as Cu^{2+} , Co^{2+} , Mn^{2+} substituted for the host ions are studied theoretically. General formulas for the resonance field shift, line width and the thermal relaxation time in nuclear (or electron) spin resonance in magnetic substances are given. T_1 and T_2 are here related to the difference between isothermal and isolated susceptibilities. Temperature dependence of T_1 and T_2 as well as magnetic field dependence of them are studied. At low temperatures they become longer rapidly (exponentially) as temperature is lowered while at high temperatures they are independent of temperature. Field dependence of the line width is of the type of $H_0^2 + H_i^2$ when the line is narrowed by spin-spin interaction among the host ion spins, or $\sqrt{H_0^2 + H_i^2}$ when the line is not narrowed, where H_i denotes the local magnetic field. Field dependence of $1/T_1$ is always like $H_0^2 + H_i^2$. The theoretical results are compared with some available experimental data on electron spin resonance. The agreement between theory and experiment seems to be not unreasonable as far as order of magnitude and qualitative characters of the line width are concerned, though experimental data are now rather scanty.

§ 1. Introduction

A certain amount of studies on the nuclear magnetic resonance in magnetic compounds have been done in recent years. These could reveal us many important informations on the properties of several para and antiferromagnetic compounds. Among them are some problems concerned with those paramagnetic salts whose magnetic ion has even number of unpaired electrons and then has no Kramers' degeneracy. As examples there are Cr^{2+} , Mn^{3+} , Fe^{2+} and Ni^{2+} ions. Under the crystalline electric field in solid their spin degeneracies are generally lifted. In an orthorhombic field all the degeneracies in the spin states are completely lifted so that the spin operator has no diagonal components in the absence of the external magnetic field. This situation may be said that the spin is quenched by the combined action of the spin-orbit coupling and the crystalline electric field. The spins have in this case only high frequency components because of the absence of the diagonal elements and won't have effect on the magnetic

resonance of nuclear spins or other kinds of electron spins substituted for host magnetic ions in the crystal. However, when the external field is set in, magnetic moments are induced on the ions owing to the polarization effect. These moments interact with nuclear spins as well as other kinds of electron spins, but to the extent much smaller than usual magnetic ions whose spins are not quenched. Some experimental studies have been carried out on this type of salts. Paramagnetic resonance of Mn^{2+} , Co^{2+} and Cu^{2+} ions placed instead of Fe^{2+} and Ni^{2+} respectively in $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ were reported first by Ôno and Hayashi¹⁾ and recently by Otsuka, Abe and Kanda²⁾. The latter authors measured also the susceptibility of $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and deduced from it the initial splittings of the spin levels. Non-resonant dispersion and absorption measurements on $(\text{Co-Ni})(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $(\text{Co-Fe})(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ have been studied by Haseda³⁾. Nuclear resonance experiments have been studied recently by Sugawara and

Kim⁴⁾ though the results are not yet conclusive.

As for the theoretical side, the idea of diminution of the resonance line width due to spin quenching was first put forth by P. W. Anderson and worked out in the case of high temperatures by one of the authors (Y. O.)⁵⁾. In the present article we shall treat the problem in more detail and from more general point of view especially taking notice of the temperature and field dependences of the line width and the relaxation time.

At first we shall give in §1 general formulas for the resonance field shift, the line width or T_2 and the thermal relaxation time T_1 due to the paramagnetic ion related with the nuclear resonance (or electron spin resonance of a different kind of ion). The problem of calculating T_1 and T_2 are then reduced to the calculation of the frequency distribution or time correlation functions of the paramagnetic spin fluctuation. The frequency distribution of the spin fluctuation for our case where the degeneracy of the spin levels are completely lifted by the crystalline electric field is studied in §3 and their low frequency components are shown to be related to the difference between the isothermal and the isolated susceptibilities, χ_T and χ_{is} . Isolated susceptibility is an adiabatic one in Ehrenfest's sense. In another word, χ_{is} appears when the populations of the energy levels are kept constant during the change of the measuring field. In §4 ($\chi_T - \chi_{is}$) is calculated for Ni^{2+} ($S=1$) and Fe^{2+} ($S=2$) salts. Numerical values are given for $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. The relaxation times T_1 and T_2 of nuclear spins as well as electron spins of different kinds of ions are discussed respectively in §5 and in §6. For the latter case the theoretical results are compared with some available experimental data. The agreement proves to be not unreasonable in the order of magnitude and in the qualitative characters of the temperature and field dependences of the relaxation times. In the last section, §7, some remarks on this problem are made.

§2. General Formulas

We shall here consider a system consisting of two kinds of spins, electronic spins of a kind of magnetic ions and nuclear spins. The

latter can, as occasion demands, be replaced by spins of different kind of magnetic ions. The resonance frequency, the line width and the relaxation time T_1 of the latter will in general be strongly affected by the former. In this section this effect is treated. For brevity we shall consider one resonating spin (hereafter called the nuclear spin) and neglect the interaction among the resonating spins. This can not only be justified when the concentration of the resonating spins is low but also be useful when the all sorts of contributions to the line width and to the relaxation time work additively. The formulas for the line width, the frequency shift and T_1 in this case have already been derived for a special case⁶⁾. We shall reproduce them in more general forms.

The Hamiltonian of the system is written as

$$\mathcal{H} = \mathcal{H}_N + \mathcal{H}_e + \mathcal{H}_{Ne}, \quad (2.1)$$

$$\mathcal{H}_N = -\gamma_N \hbar \mathbf{I} \cdot \mathbf{H}_0, \quad (2.2)$$

$$\mathcal{H}_{Ne} = \gamma_N \gamma_e \hbar^2 \sum_{\nu=1}^3 I_\nu \sum_j \sum_{\mu=1}^3 \Phi_{j\nu\mu} S_{j\mu}, \quad (2.3)$$

where $\mathcal{H}_e$ is the Hamiltonian of the electron spin system which can, as circumstances require, include the lattice vibrations, $\mathcal{H}_N$ that of the nuclear spin, and $\mathcal{H}_{Ne}$ that of the interaction between the nuclear spin and the electron spins. $\mathbf{I}$ denotes the nuclear spin, S_j the j -th electron spin, γ_N and γ_e the gyromagnetic ratios of the nuclear and the electronic spins, $\mathbf{H}_0$ the external magnetic field. The suffixes $\mu, \nu=1, 2, 3$, represent respectively the x, y, z components of vectors and tensors. $\Phi_{j\nu\mu}$ is the coupling constant of the nuclear spin to the j -th electron spin which is written in the case of pure dipole-dipole interaction as

$$\Phi_{j\nu\mu} = \sum_{\nu'} \frac{1}{2} g_{\nu\nu'} r_j^{-3} (\delta_{\mu\nu'} - 3t_j^\mu t_j^{\nu'}) \quad (2.4)$$

where $g_{\nu\nu'}$ is a component of the g -tensor, $\mathbf{r}_j (r_j = |\mathbf{r}_j|)$ the position vector of the j -th magnetic ion, assuming the nuclear spin is located at the origin, $t_j^\nu = \mathbf{r}_j^\nu / r_j$ its direction cosine.

Dividing an electron spin into two parts, i.e. the thermal equilibrium value and the deviation from it:

$$S_{j\nu} = \langle S_{j\nu} \rangle + \delta S_{j\nu}, \quad \dots \quad (2.5)$$

(2.1) (2.3) can be rewritten as

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}' + \mathcal{H}_e, \quad (2.6)$$

$$\mathcal{H}_0 = -\gamma_N \hbar \mathbf{I} \cdot \mathbf{H}, \quad \dots \quad (2.7)$$

$$\mathcal{H}' = -\gamma_N \hbar \mathbf{I} \cdot \delta \mathbf{H}, \quad (2.8)$$

where $\mathbf{H}$ is the thermal average of the total magnetic field at the nucleus and $\delta \mathbf{H}$ the fluctuating part of the local magnetic field. They are written

$$H_\nu = H\alpha_\nu = H_{0\nu} - \gamma_e \hbar \sum_j \sum_{\mu=1}^3 \Phi_j^{\nu\mu} \langle S_{j\mu} \rangle, \quad (2.9)$$

$$\delta H_\nu = -\gamma_e \hbar \sum_j \sum_{\mu=1}^3 \Phi_j^{\nu\mu} \delta S_{j\mu}, \quad (2.10)$$

$\alpha_1, \alpha_2, \alpha_3$ being the direction cosines of $\mathbf{H}$. The second term of (2.9) represents the shift of the resonance field. By a orthogonal coordinate-transformation $\{\alpha_{\nu\mu}\}$ we take the direction of $\mathbf{H}$ as the new third axis, the quantization axis for the nuclear spin. The components of $\mathbf{I}$ and $\delta \mathbf{H}$ in the new coordinate system are written as J_ν and K_ν . They satisfy

$$\left. \begin{aligned} I_\mu &= \sum_\nu J_\nu \alpha_{\nu\mu}, \\ \delta H_\mu &= \sum_\nu K_\nu \alpha_{\nu\mu}, \end{aligned} \right\} \quad (2.11)$$

where $\alpha_{3\nu} = \alpha_\nu$. In the new coordinate system, the Hamiltonians are expressed as follows:

$$\mathcal{H}_0 = -\gamma_N \hbar J_3 H \equiv -\hbar \omega_0 J_3, \quad (2.7')$$

$$\begin{aligned} \mathcal{H} &= -\gamma_N \hbar \sum_{\nu=1}^3 J_\nu K_\nu \\ &= -\gamma_N \hbar [J_3 K_3 + \frac{1}{2}(J_+ K_- + J_- K_+)], \end{aligned} \quad (2.8')$$

where $J_\pm = J_1 \pm iJ_2$ and $K_\pm = K_1 \pm iK_2$.

The shape of the resonance absorption line is obtained as follows⁷⁾:

$$I(\omega) = \int_{-\infty}^{\infty} \exp[i\omega t - \phi(t)] dt, \quad (2.12)$$

$$\phi(t) = \gamma_N \hbar \int_0^t d\tau (t-\tau) \{F_0(\tau) + e^{i\omega_0 \tau} F_1(\tau)\}, \quad (2.13)$$

$$\begin{aligned} F_0(t) &= \langle \{K_3(t) K_3\} \rangle \\ &= \sum_\nu \sum_{\nu'} \alpha_\nu \alpha_{\nu'} \langle \{\delta H_\nu(t) \delta H_{\nu'}\} \rangle, \end{aligned} \quad (2.14)$$

$$\begin{aligned} F_1(t) &= \langle \{K_+(t) K_-\} \rangle / 2 \\ &= \sum \sum \frac{1}{2} (\delta_{\nu\nu'} - \alpha_\nu \alpha_{\nu'}) \langle \{\delta H_\nu(t) \delta H_{\nu'}\} \rangle \end{aligned} \quad (2.15)$$

where

$$\delta \mathbf{H}(t) = \exp(it \mathcal{H}_0 / \hbar) \delta \mathbf{H} \exp(-it \mathcal{H}_0 / \hbar). \quad (2.16)$$

The relaxation time T_1 becomes

$$\begin{aligned} 1/T_1 &= (\gamma_N/2)^2 \int_{-\infty}^{\infty} dt \cos \omega_0 t [\langle K_+(t) K_- \rangle + \langle K_-(t) K_+ \rangle] \\ &= \gamma_N^2 \int_{-\infty}^{\infty} dt \cos \omega_0 t F_1(t). \end{aligned} \quad (2.17)$$

$\langle \{\delta H_\nu(t) \delta H_{\nu'}\} \rangle$ are expressed as follows neglecting the small effect of the modulation of

the coordinate by lattice vibrations:

$$\begin{aligned} &\langle \{\delta H_\nu(t) \delta H_{\nu'}\} \rangle \\ &= (\gamma_e \hbar)^2 \sum_{j,k} \sum_{\mu,\mu'} \Phi_j^{\nu\mu} \Phi_k^{\nu'\mu'} \langle \{\delta S_{j\mu}(t) \delta S_{k\mu'}\} \rangle, \end{aligned} \quad (2.18)$$

When the correlations between two different spin fluctuations are neglected, which is actually the case in the usual paramagnetic state, (2.18) reduces itself simply to

$$\begin{aligned} &\langle \{\delta H_\nu(t) \delta H_{\nu'}\} \rangle \\ &= (\gamma_e \hbar)^2 \sum_{j>k} \sum_{\mu,\mu'} \Phi_j^{\nu\mu} \Phi_j^{\nu'\mu'} \langle \{\delta S_{j\mu}(t) \delta S_{j\mu'}\} \rangle. \end{aligned} \quad (2.19)$$

§ 3. Fluctuations of the Electron Spins

We shall deal with the time correlation functions of the spin fluctuations in the case where the degeneracy of the electron spin states are completely lifted by the combined influence of the spin-orbit coupling and the crystalline electric field. The Hamiltonian of the electron spin system is expressed as follows:

$$\mathcal{H}_e = \mathcal{H}_{e0} + \mathcal{H}_{e'}, \quad (3.1)$$

$$\mathcal{H}_{e0} = \sum_j \mathcal{H}_j = \sum_j [S_j \cdot A_j \cdot S_j + \mu_B S_j \cdot \mathbf{g}_j \cdot \mathbf{H}_0], \quad (3.2)$$

$$\mathcal{H}_{e'} = \sum_{j>k} \mathcal{H}_{jk}. \quad (3.3)$$

$\mathcal{H}_{e0}$ is the one-spin energy and $\mathcal{H}_{e'}$ is the interaction energy. A_j denotes the tensor expressing the fine structure coupling under the crystalline electric field, $\mathbf{g}_j$ the g -tensor.

When $\mathcal{H}_{e'}$ is smaller than $\mathcal{H}_{e0}$, we can use the perturbation method to calculate the motion of the spin fluctuations and then their correlation functions⁷⁾. We get

$$\langle \{\delta S_{j\mu}(t) \delta S_{j\nu}\} \rangle = G_{\mu\nu}^j(t) = \sum_{n=0}^{\infty} G_{\mu\nu}^{j(n)}(t), \quad (3.4)$$

$$\begin{aligned} G_{\mu\nu}^{j(n)}(t) &= (i\hbar)^{-n} \int_0^t dt_1 \int_0^{t_1} dt_2 \cdots \int_0^{t_{n-1}} dt_n \langle [\{S_{j\mu}(t); \\ &\quad \mathcal{H}_e(t_1), \mathcal{H}_{e'}(t_2), \dots, \mathcal{H}_{e'}(t_n)\} S_{j\nu}] \rangle \\ &\quad - \delta_{n0} \langle S_{j\mu} \rangle \langle S_{j\nu} \rangle, \end{aligned} \quad (3.5)$$

$$S_{j\mu}^0(t) = \exp(it \mathcal{H}_{e0} / \hbar) S_{j\mu} \exp(-it \mathcal{H}_{e0} / \hbar), \quad (3.6)$$

$$\mathcal{H}_{e'}(t)$$

$$= \exp(it \mathcal{H}_{e0} / \hbar) \mathcal{H}_{e'} \exp(-it \mathcal{H}_{e0} / \hbar), \quad (3.7)$$

where

$$[A; B, C, \dots, K] = [[\dots[A, B], C] \dots], K].$$

The suffix j specifying the j -th spin will

hereafter be neglected.

We shall take such a representation as to diagonalize $\mathcal{H}_{e0}$:

$$\mathcal{H}_{e0} = \begin{pmatrix} E_1 & & & & & & 0 \\ & E_2 & & & & & \\ & & \ddots & & & & \\ 0 & & & E_m & & & \\ & & & & \ddots & & \\ & & & & & E_{2s+1} & \end{pmatrix}, \quad (3.8)$$

where it is assumed that there is no degeneracy of the energy levels. $\langle S \rangle$ and $G_{\mu\nu}^{(0)}(t)$ are then expressed as follows:

$$\langle S_\mu \rangle = \sum_m f_m(S_\mu)_{mm}, \quad (3.9)$$

$$f_m = \exp(-E_m/kT) / \sum_n \exp(-E_n/kT), \quad (3.10)$$

$$\begin{aligned} G_{\mu\nu}^{(0)}(t) &= \sum_m f_m(S_\mu)_{mm}(S_\nu)_{mm} \\ &\quad - \sum_{n,m} f_n f_m(S_\mu)_{nn}(S_\nu)_{mm} \\ &\quad + \sum_{n \neq m} \frac{f_n + f_m}{2} \exp(i\omega_{nm}t)(S_\mu)_{nm}(S_\nu)_{mn}, \end{aligned} \quad (3.11)$$

$$\hbar\omega_{nm} = E_n - E_m. \quad (3.12)$$

To get $G_{\mu\nu}(t)$ we have in principle to extend the calculation to the higher order terms of the perturbation series. However, $G_{\mu\nu}(t)$ may be considered as to have a form (3.11) multiplied, term by term, by such functions as to satisfy the following condition:

$$f(t) = \begin{cases} 1 & \text{for } t=0, \\ 0 & \text{for } t \rightarrow \infty. \end{cases} \quad (3.13)$$

In many cases we anticipate by physical insight the form of $f(t)$ and then determine the parameters from lower order terms of the perturbation series. The possible form of $f(t)$ may be $\exp(-\frac{1}{2}\omega_e^2 t^2)$, $\exp(-|t|/\tau_e)$ and their intermediary, etc., where $\hbar\omega_e$ and $\hbar/\tau_e$ are of the order of magnitude of the effective spin-spin interaction. In our case the former form may be taken when the concentration of magnetic ions is not low, and the latter when the concentration of magnetic ions is low or when

the spin-lattice relaxation gives the dominating mechanism of the fluctuating motions of spins⁹. When the former type, the Gaussian function, is taken, we need only to know the second moment which is expected to depend scarcely on temperature. Actually we calculated it in the special case where $S=1$ (Ni^{2+}) and H_0/z -axis, and confirmed that the temperature dependence of ω_e is very weak and its order of magnitude does not appreciably change in all the temperature range.

We shall here simply make an approximating assumption:

$$G_{\mu\nu}(t) = G_{\mu\nu}^{(0)}(t)f(t), \quad (3.14)$$

where $f(t)$ satisfies the condition (3.13) and its decay time is of the order of magnitude of $\hbar$ divided by the effective spin-spin interaction and does not depend on temperature. The shape of $f(t)$ will be assumed properly according to the case. This assumption, though simple, is sufficient for the qualitative discussions and is useful even for the quantitative order estimation.

We shall here remark on the correction terms to $G_{\mu\nu}^{(0)}(t)$ arising from the higher order terms of the perturbation series. This correction to zero frequency component is not always negligible as compared to the first and the second terms of (3.11), which are small themselves. The ratio of the zero-frequency component of this higher order correction to that of $G_{\mu\nu}^{(0)}$ may be given by (spin-spin interaction energy/Zee-man energy)². Therefore, the results of this and the following sections are applicable not only to the case where the Zeeman energy is much larger than the spin-spin interaction energy but also to the case where they are of comparable order of magnitude provided we replace H_0^2 by $H_0^2 + H_i^2$, H_i being the effective internal magnetic field.*

* We have calculated this correction for the simple case where there is only one kind of magnetic ion site in the unit cell, and the static field is applied along one of the magnetic principal axes. The results are as follows:

$$G_{\mu\mu}(0) = \frac{g^2\mu_B^2}{X_{\mu}^2 + (g\mu_B H_0)^2} \left[H_0^2 F_{\mu\mu} + \frac{X_{\mu}^2}{X_{\mu}^2 + (g\mu_B H_0)^2} H_i^2 F_{\mu\mu}' \right],$$

in which $F_{\mu\mu}$ and X_{μ} are given by (4.6), (4.7), and H_i^2 and $F_{\mu\mu}'$ are given in the following table.

	H_0/x	H_0/y	H_0/z
$H_{i\mu}^2$	$\frac{3}{2} \sum_k \frac{(g\mu_B)^2 y_{jk}^2 z_{jk}^2}{r_{jk}^{10}}$	$\frac{3}{2} \sum_k \frac{(g\mu_B)^2 z_{jk}^2 x_{jk}^2}{r_{jk}^{10}}$	$\frac{3}{2} \sum_k \frac{(g\mu_B)^2 x_{jk}^2 y_{jk}^2}{r_{jk}^{10}}$
$F_{\mu\mu}'$	$3(f_1 + f_2)f_3$	$3(f_2 + f_3)f_1$	$3(f_1 + f_3)f_2$

We shall now further study the properties of $G_{\mu\nu}^{(0)}(t)$. The first and the second terms of (3.11) are secular terms and the third is a non-secular term. One can easily see from (2.13), (2.14), (2.15) and (2.17) that the contribution of the non-secular term to the line width and $1/T_1$ is far smaller than that of the secular terms provided $|\omega_{nm}|$ and $|\omega_0 + \omega_{nm}|$ are sufficiently larger than ω_e whose order of magnitude is that of the inverse of the decay time of $f(t)$. This condition is satisfied in many cases; when all the energy level separations are larger than the spin-spin interaction, it is satisfied in almost all the cases of nuclear resonance and in the case of the electron spin resonance of different ions except when the resonance frequency is near to one of the resonance frequencies of the host ion spins. In the following treatment we shall confine ourselves to the case where this condition is satisfied. Neglecting then the third term of (3.11) we can write

$$G_{\nu\nu}^{(0)}(t) = \langle (S_\mu)_a (S_\nu)_a \rangle - \langle S_\mu \rangle \langle S_\nu \rangle, \quad (3.15)$$

where $(\)_a$ means the diagonal component. This can further be related to the isothermal and the isolated susceptibility tensors as follows:

$$\begin{aligned} g_\mu g_\nu \mu_B^2 G_{\mu\nu}^{(0)}(t) &= \sum_m f_m \frac{\partial E_m}{\partial H_\mu} \frac{\partial E_m}{\partial H_\nu} \\ &\quad - \sum_m f_m \frac{\partial E_m}{\partial H_\mu} \sum_n f_n \frac{\partial E_n}{\partial H_\nu} \\ &= \left\langle \frac{\partial E}{\partial H_\mu} \frac{\partial E}{\partial H_\nu} \right\rangle - \left\langle \frac{\partial E}{\partial H_\mu} \right\rangle \left\langle \frac{\partial E}{\partial H_\nu} \right\rangle \\ &= kT(\chi_T - \chi_{ts})_{\mu\nu}. \end{aligned} \quad (3.16)$$

From the properties of $(\chi_T - \chi_{ts})$ qualitative discussions on the general properties of T_1 and T_2 can be given.

(1) At low temperatures where $kT < \Delta E$, ΔE being the energy separation between the lowest two levels, T_1 and T_2 increase very rapidly (exponentially) as temperature is lowered, since $(\chi_T - \chi_{ts})$ is proportional to $e^{-\Delta E/kT}$ at these temperatures.

(2) At high temperatures where kT is larger than the overall separation of the spin levels, T_1 and T_2 are independent of temperature

since $kT(\chi_T - \chi_{ts})$ is there independent of temperature.

(3) When the Zeeman energy is smaller than the initial splitting, $(S)_a \propto H_0$ and $G_{\mu\nu}(t) \propto H_0^2$ so that we have

$$1/T_2 \propto H_0, \quad (3.17)$$

provided there is no narrowing effect, i.e. $\{|\chi_T F_0|\}^{1/2} > \omega_e$. With the narrowing effect we have stronger field dependence of T_2 . In the case of extreme narrowing, i.e. $\{|\chi_T F_0|\}^{1/2} \ll \omega_e$, we have

$$1/T_2 \propto H_0^2. \quad (3.18)$$

As for the field dependence of T_1 we expect

$$1/T_1 \propto H_0^2, \quad (3.19)$$

except for the factor arising from the field dependence of ω_0 . In the case of nuclear resonance (3.19) will represent the correct field dependence of T_1 , while for electron spin resonance the factor coming from the field dependence of ω_0 will be important.

Before concluding this section, we shall transform (3.16) into the form convenient for later use. When the Zeeman energy is smaller than the initial splitting the energy eigenvalues given by (3.8) are written as follows taking up to the second order terms with respect to the external magnetic field:

$$E_m = E_m^0 - \frac{1}{2} \sum_{\nu=1}^3 A_{\nu m} H_\nu^2. \quad (3.20)$$

From (3.16) we get

$$kT(\chi_T - \chi_{ts})_{\mu\nu} = \langle A_\mu A_\nu \rangle - \langle A_\mu \rangle \langle A_\nu \rangle H_\mu H_\nu. \quad (3.21)$$

§ 4. $(\chi_T - \chi_{ts})$ for $\text{Ni}^{2+}(S=1)$ and $\text{Fe}^{2+}(S=2)$

The spin Hamiltonian of a magnetic ion in an orthorhombic crystalline field can be written in a usual form:

$$\begin{aligned} \mathcal{H} &= -DS_z^2 - E(S_x^2 - S_y^2) \\ &\quad + \mu_B(g_x H_x S_x + g_y H_y S_y + g_z H_z S_z), \end{aligned} \quad (4.1)$$

where x , y , and z axes are the principal axes of the crystalline electric field. We shall calculate $kT(\chi_T - \chi_{ts})$ by using (3.16) and (3.21).

(I) $\text{Ni}^{2+}(S=1)$

The expressions for χ_T and χ_{ts} as well as χ_s (adiabatic susceptibility in a thermodynamical

If we assume that the crystal has symmetry higher than cubic the magnitude of H_i^2 is one-twelfth of the square of what is usually called an internal field. [See, for instance, Eq. (14) of Van Vleck's paper; Phys. Rev. **74** (1948) 1168.]

$$H_i^2 = \frac{1}{10} g^2 \mu_B^2 \sum_k r_{jk}^{-6} = \frac{1}{12} \times \left[\frac{3}{5} S(S+1) g^2 \mu_B^2 \sum_k r_{jk}^{-6} \right]_{S=1}.$$

cal sense) have already been obtained for this case⁹). Some numerical calculations for the case of $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ have also been carried out⁹). Here we reproduce some of the results in which the terms up to the second order with respect to the external magnetic field H_0 are taken into account.

The energy eigenvalues are expressed in the form of (3.20) of which the values of the constants are given in the following table:

m	E_m^0	A_{zm}	A_{ym}	A_{xm}
1	$-D-E$	$\frac{2g_z^2\mu_B^2}{D+E}$	0	$\frac{g_z^2\mu_B^2}{E}$
2	0	$-\frac{2g_z^2\mu_B^2}{D+E}$	$-\frac{2g_y^2\mu_B^2}{D-E}$	0
3	$-D+E$	0	$\frac{2g_y^2\mu_B^2}{D-E}$	$-\frac{g_z^2\mu_B^2}{E}$

(4.2)

From this we get

$$\langle S_y \rangle = \frac{g_y^2\mu_B^2}{X_y} h_y H, \quad (4.3)$$

$$h_1 = f_1 - f_2, \quad h_2 = f_3 - f_2, \quad h_3 = f_1 - f_3. \quad (4.4)$$

$$kT(\chi_T - \chi_{is})_{\mu\nu} = \frac{g_\mu^2 g_\nu^2 \mu_B^4 H_\mu H_\nu}{X_\mu X_\nu} F_{\mu\nu}, \quad (4.5)$$

$$\left. \begin{aligned} F_{11} &= f_1 + f_2 - (f_1 - f_2)^2, \\ F_{12} &= f_2 - (f_2 - f_1)(f_2 - f_3), \\ F_{22} &= f_2 + f_3 - (f_2 - f_3)^2, \\ F_{23} &= -f_3 + (f_3 - f_2)(f_3 - f_1), \\ F_{33} &= f_3 + f_1 - (f_3 - f_1)^2, \\ F_{31} &= f_1 - (f_1 - f_3)(f_1 - f_2), \end{aligned} \right\} \quad (4.6)$$

$$X_1 = (D+E)/2, \quad X_2 = (D-E)/2, \quad X_3 = E. \quad (4.7)$$

The numerical results for $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ are shown in Fig. 1. For the values of D , E and g we used the experimental values at 90°K .¹⁰

$$D = 1.99 \text{ cm}^{-1}, \quad E = 0.486 \text{ cm}^{-1}, \quad g = 2.25. \quad (4.8)$$

The contribution of Zeeman energy to the Boltzmann factors are neglected in calculating numerical values in Fig. 1.

(II) $\text{Fe}^{2+}(S=2)$

The energy eigenvalues are expressed by (3.20) up to the second order with respect to the external magnetic field H_0 . The values of the constants are shown in the following table:

m	E_m^0	A_{zm}	A_{ym}	A_{xm}
1	$-2D(1+\sqrt{1+\eta^2})$	$\frac{g_z^2\mu_B^2(c+\sqrt{3}s)^2}{D\left(\frac{1}{2}+\sqrt{1+\eta^2}-\frac{\sqrt{3}}{2}\eta\right)}$	$\frac{g_y^2\mu_B^2(c-\sqrt{3}s)^2}{D\left(\frac{1}{2}+\sqrt{1+\eta^2}+\frac{\sqrt{3}}{2}\eta\right)}$	$\frac{4g_z^2\mu_B^2c^2}{D(\sqrt{1+\eta^2}-1)}$
2	$-4D$	$\frac{2g_z^2\mu_B^2}{D(3+\sqrt{3}\eta)}$	$\frac{2g_y^2\mu_B^2}{D(3-\sqrt{3}\eta)}$	$\frac{4g_z^2\mu_B^2}{D}\left\{\frac{s^2}{\sqrt{1+\eta^2}+1}-\frac{c^2}{\sqrt{1+\eta^2}-1}\right\}$
3	$-D(1+\sqrt{3}\eta)$	$\frac{g_z^2\mu_B^2}{D}\left\{\frac{(s-\sqrt{3}c)^2}{\sqrt{1+\eta^2}+\frac{\sqrt{3}}{2}\eta-\frac{1}{2}}-\frac{(c+\sqrt{3}s)^2}{\sqrt{1+\eta^2}-\frac{\sqrt{3}}{2}\eta+\frac{1}{2}}\right\}$	$-\frac{2g_y^2\mu_B^2}{D(3-\sqrt{3}\eta)}$	$\frac{g_z^2\mu_B^2}{D\sqrt{3}\eta}$
4	$-D(1-\sqrt{3}\eta)$	$-\frac{2g_z^2\mu_B^2}{D(3+\sqrt{3}\eta)}$	$\frac{g_y^2\mu_B^2}{D}\left\{\frac{(s+\sqrt{3}c)^2}{\sqrt{1+\eta^2}-\frac{\sqrt{3}}{2}\eta+\frac{1}{2}}-\frac{(c-\sqrt{3}s)^2}{\sqrt{1+\eta^2}+\frac{\sqrt{3}}{2}\eta+\frac{1}{2}}\right\}$	$-\frac{g_z^2\mu_B^2}{D\sqrt{3}\eta}$
5	$2D(\sqrt{1+\eta^2}-1)$	$-\frac{g_z^2\mu_B^2(s-\sqrt{3}c)^2}{D\left(\sqrt{1+\eta^2}+\frac{\sqrt{3}}{2}\eta-\frac{1}{2}\right)}$	$-\frac{g_y^2\mu_B^2(s+\sqrt{3}c)^2}{D\left(\sqrt{1+\eta^2}-\frac{\sqrt{3}}{2}\eta-\frac{1}{2}\right)}$	$-\frac{4g_z^2\mu_B^2s^2}{D(\sqrt{1+\eta^2}+1)}$

where

$$\eta = \sqrt{3} E/D, \quad c = \cos \theta, \quad s = \sin \theta, \quad \tan 2\theta = \eta. \tag{4.10}$$

The values of $kT(\chi_T - \chi_{ts})$ are calculated by using (3.21). The numerical results for $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ are shown in Table I. The values of D and E are taken from Ohtsuka, Abe and Kanda's result²⁾:

$$D=14.5 \text{ cm}^{-1}, \quad E=5.86 \text{ cm}^{-1}. \quad (4.11)$$

The anisotropy of g is neglected and the average value,

$$g_{\text{av}}=2.14, \quad (4.12)$$

are taken. The contribution of the Zeeman energy to the Boltzmann factors are here also neglected.

§ 5. Nuclear Magnetic Resonance

The motion of the electron spins are usually much faster than that of nuclear spins in the local field, so that the narrowing condition for the nuclear resonance line stated in § 3 is almost always satisfied. The neglect of the non-secular perturbation (nondiagonal components of the electron spins) are also justified. The line shape therefore is Lorentzian and T_1 and T_2 are of the same order of magnitude. By using the formulas in § 2 we get

(a) for $f(t)=\exp(-\frac{1}{2}\omega_e^2 t^2)$,

$$1/T_2=(\pi/2)^{1/2}(\gamma_N^2/\omega_e)[F_0'(0)+F_1'(0)\exp(-\frac{1}{2}\omega_0^2/\omega_e^2)], \quad (5.1)$$

$$1/T_1=(2\pi)^{1/2}\gamma_N^2 F_1'(0)\exp(-\frac{1}{2}\omega_0^2/\omega_e^2)/\omega_e, \quad (5.2)$$

$$(\text{usually } \exp(-\frac{1}{2}\omega_0^2/\omega_e^2)\sim 1)$$

(b) for $f(t)=\exp(-|t|/\tau_e)$,

$$1/T_2=\gamma_N^2 \tau_e [F_0'(0)+F_1'(0)/(1+\omega_0^2 \tau_e^2)], \quad (5.3)$$

$$1/T_1=2\gamma_N^2 \tau_e F_1'(0)/(1+\omega_0^2 \tau_e^2). \quad (5.4)$$

$$(\text{usually } (1+\omega_0^2 \tau_e^2)\sim 1)$$

where

$$F_0'(0)=\sum_j \sum_{\nu, \nu'} P_{0j}{}^{\nu\nu'} kT(\chi_T - \chi_{ts})_{\nu\nu'} / g_\nu g_{\nu'} \mu_B^2, \quad (5.5)$$

$$F_1'(0)=\sum_j \sum_{\nu, \nu'} P_{1j}{}^{\nu\nu'} kT(\chi_T - \chi_{ts})_{\nu\nu'} / g_\nu g_{\nu'} \mu_B^2, \quad (5.6)$$

$$P_{0j}{}^{\nu\nu'} = (\gamma_e \hbar)^2 \sum_{\mu, \mu'} \alpha_\mu \alpha_{\mu'} \Phi_j^{\mu\nu} \Phi_j^{\mu'\nu'}, \quad (5.7)$$

$$P_{1j}{}^{\nu\nu'} = \frac{1}{2}(\gamma_e \hbar)^2 \sum_{\mu, \mu'} (\delta_{\mu\mu'} - \alpha_\mu \alpha_{\mu'}) \Phi_j^{\mu\nu} \Phi_j^{\mu'\nu'}. \quad (5.8)$$

$P_{0j}{}^{\nu\nu'}$ and $P_{1j}{}^{\nu\nu'}$ depend in a complicated way on the direction of the magnetic field and on the arrangements of the magnetic ions. When the interaction between the nuclear spin and the electron spins are of purely dipolar character, we may estimate

$$P_{0j}{}^{\nu\nu'} \sim P_{1j}{}^{\nu\nu'} \sim g^2 \mu_B^2 / r_j^3,$$

except for the angular dependent factor whose order of magnitude is 1.

We shall make, for example, an order estimation of T_1 and T_2 of protons of the water molecules in $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. In this case one magnetic ion nearest to the considering proton makes a dominant contribution. Estimating $P_{0j}{}^{\nu\nu'} \sim P_{1j}{}^{\nu\nu'} \sim 10^6$, we get

$$1/T_1 \sim 1/T_2 \sim (10^{15}/\omega_e) \sum_{\nu, \nu'} kT(\chi_T - \chi_{ts})_{\nu\nu'} / g^2 \mu_B^2. \quad (5.9)$$

For $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ we estimate $\omega_e \sim 5 \times 10^9$ from the paramagnetic resonance line width¹⁰⁾. For $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ we shall here assume $\omega_e \sim 10^{10}$ since no data is available, though it

will be estimated from a measurement of the nuclear relaxation time stated here. In Tables II and III the relaxation time in the case where the external field is applied along the x , y , and z axes are given. The numerical values in the Tables II and III are only of order of magnitude significance, though the temperature dependence is reliable. We can of course make more precise calculations taking account of the exact arrangement of the ions in the crystals by using (5.1)~(5.6).

Table II. $T_1 \sim T_2$ (in sec.) for protons in H_2O in $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ at $H_0 = 3000$ gauss.
($\omega_e \simeq 5 \times 10^9$)

$T^\circ\text{K}$	H_0/x	H_0/y	H_0/z	$T^\circ\text{K}$	H_0/x	H_0/y	H_0/z

				1	110	220	0.22

As one sees in Tables II and III the temperature and the magnetic field dependences and the anisotropies of T_1 and T_2 seem especially to be interesting. A remarkable temperature dependence of T_1 and T_2 is expected at liquid helium temperatures for $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, though it is expected below 1°K for $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$.

§ 6. Paramagnetic Resonance and Relaxation

In this section we shall chiefly be concerned with the paramagnetic resonance and relaxation of ions like Mn^{2+} , Co^{2+} , Cu^{2+} , etc., which are diluted in the salts of Fe^{2+} or Ni^{2+} . Let Mn^{2+} and Fe^{2+} be the representatives of the resonating and the host ion spins, respectively. If all the resonance frequency differences of Mn^{2+} and Fe^{2+} are much greater than the interaction energy (dipolar or exchange) divided by $\hbar$, the effect of nondiagonal elements (high frequency components) of Fe^{2+} spin on the resonance spectrum of Mn^{2+} can be neglected, i.e., (3.15) and (3.16) are satisfied. Further, if the condition, $\langle (\delta S)_a^2 \rangle \ll S(S+1)$, is satisfied for Fe^{2+} spins, their contribution to the Mn^{2+} resonance line width is narrowed by the interaction (dipolar or exchange) among Fe^{2+} spins. The above inequality expresses

that the *effective* $\text{Fe}^{2+} - \text{Mn}^{2+}$ interaction is smaller than the $\text{Fe}^{2+} - \text{Fe}^{2+}$ interaction. This is valid when the initial splittings of Fe^{2+} spin levels are much larger than the Zeeman energy. In this case the line shape becomes Lorentzian, and the expressions for T_1 and T_2 are the same as Eq. (5.3) and (5.4) except that the r_N there should be replaced by r_e . One should be careful, however, that the neglect of high frequency components of Fe^{2+} spins in the expression of T_1 is not so good an approximation as in the NMR case. In the case where $\omega_0 \gg \omega_e$, the second term in the right-hand side of the equations of T_2 (Eq. (5.1) and (5.3)) can be neglected.

Let us first make simple order estimations and qualitative discussions. When the Mn^{2+} resonance line width is not narrowed by the $\text{Fe}^{2+} - \text{Fe}^{2+}$ interaction, the width is of the order,

$$\gamma_e V \sqrt{[F_0'(0)]}, \quad (6.1)$$

which, as compared to the value when the Fe^{2+} spins are assumed free, is reduced by a factor of $(\delta S)_a/S$. When $(\delta S)_a/S \ll 1$ is satisfied, the line width is necessarily narrowed since ω_e is of the same order of magnitude

as in the case where Fe^{2+} spins are free*, and we obtain the following expression for T_2 :

$$\frac{1}{T_2} \simeq \left(\frac{(\partial S)_a}{S} \right)^2 (1/T_2)_{\text{free spin}} = \frac{kT(\chi_T - \chi_{ts})}{g^2 \mu_B^2 S^2} (1/T_2)_{\text{free spin}}, \quad (6.2)$$

where $(1/T_2)_{\text{free spin}}$ is a measure for line width of Mn^{2+} resonance when the Fe^{2+} spins are assumed free. The exchange interaction between Mn^{2+} and Fe^{2+} spins also contributes to $(1/T_2)_{\text{free spin}}$. The line width will show strong temperature dependence (at low temperatures) and field dependence like $H_0^2 + H_i^2$ as in the NMR case.

T_1 shows different behaviors in cases (a) and (b) in § 5. Its temperature dependence is the same as that of T_2 , but the field dependence is as follows:

in case (a),

$$1/T_1 \propto (H_0^2 + H_i^2) \exp(-\frac{1}{2} \gamma_e^2 H_0^2 / \omega_e^2), \quad (6.3)$$

which has a minimum near $H_0 \sim H_i$, and

in case (b),

$$1/T_1 \propto (H_0^2 + H_i^2) \tau_e / (1 + \gamma_e^2 H_0^2 \tau_e^2), \quad (6.4)$$

and when τ_e depends weakly on H_0 , so is T_1 . When the spin-lattice mechanism determines τ_e , the decay time of $f(t)$, its field dependence plays an important role. It should also be noticed that the contribution of high frequency components of Fe^{2+} spins to $(1/T_1)$ can not necessarily be neglected.

In the following we shall discuss, as some examples, the line width and the relaxation time of Mn^{2+} which are substituted for Fe^{2+} or Ni^{2+} in the salts of $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$. However, there are 2, 2 and 4 non-equivalent magnetic ion sites respectively in these salts, which makes the exact calculation of the line width and the relaxation time very much complicated though possible. So we here discuss about their order of magnitudes and

* We should notice here that ω_e is of order of magnitude of the mean frequency of spin diffusion which decreases when one applies the magnetic field of a certain magnitude provided that there are some different sites of magnetic ions in a unit cell as is usually the case. It is because the ions in the different sites have usually different energy levels under the magnetic field, which causes to prevent the spin diffusion. In the following statement this effect is not taken into account.

Though Eq. (6.2) is valid, strictly speaking, when all the ions are equivalent, it may be allowed to use it for order estimations.

qualitative characters of temperature and field dependences.

(i) $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$.

Details of the crystal structure, the orientation of the magnetic principal axes etc, are found in ref. 2). If we take the external magnetic field to be 3000 gauss, we obtain from Eq. (6.2) and Table I the following:

for $H_0 \perp K_2$,

$$1/T_2 \lesssim 10^{-2} (1/T_2)_{\text{free spin}} \quad \text{at } 4^\circ\text{K},$$

$$1/T_2 \lesssim 10^{-3} (1/T_2)_{\text{free spin}} \quad \text{at } 2^\circ\text{K},$$

and for $H_0 \parallel K_2$,

$$1/T_2 \sim 10^{-6} (1/T_2)_{\text{free spin}} \quad \text{at } 4^\circ\text{K},$$

$$1/T_2 \sim 10^{-6} (1/T_2)_{\text{free spin}} \quad \text{at } 2^\circ\text{K}.$$

As one can readily see from the Table I (§ 4), the line width at room temperature is, when $H_0 \perp K_2$, the same order of magnitude as (or a little greater than) the value at 4°K , while it becomes about 10 times greater than the value at 4°K when $H_0 \parallel K_2$.

If we take the line width of free Fe^{2+} spins, $(\Delta H)_{\text{free spin}}$, to be 700 gauss, the line width of Mn^{2+} in this salt is always less than 7 gauss at liquid helium temperatures, decreasing rapidly when the temperature is further lowered. Its field dependence is like $H_0^2 + H_i^2$. (H_i being several hundred gauss).

One can, if necessary, calculate the line width, taking into account the effect of anisotropy arising from the arrangement of Fe^{2+} around Mn^{2+} . However, it is clear from above rough estimations that, Mn^{2+} — Fe^{2+} interaction mechanism is insufficient to explain the whole line width obtained in Ohtsuka et al's experiment, so long as the initial splittings of the spin levels they obtained are used. It is certain that this mechanism contributes to the line width, but very weak magnetic field dependence and the very weak temperature dependence of the observed line width may suggest that the main contribution comes from another mechanism. However, the qualitative characters of the temperature and field dependences of the field dependent part of the line width seem to favor our theory**.

** Ohtsuka et al as well as Hayashi, referred to below, obtained the field dependence of the line width by measuring the widths of several resolved fine and hyperfine components of Mn^{2+} resonance lines, varying the static magnetic field and keeping the resonance frequency constant, while our theory deals with the field dependence of the line width of free spins. However, the correction owing to this different situations turned out to be of minor importance after careful examination.

(ii) $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$.

Concerning this salt all the necessary data are at hand¹⁰). From Eq. (6.2) and Fig. 1 in § 4, the line width for $H_0=3000$ gauss has been calculated. We obtain the following:

for $H_0 \parallel K_1$,

$$1/T_2 \sim 0.3(1/T_2)_{\text{free spin}}$$

for room temp. $\sim$ liq. He temp.,

$$\sim 0.05(1/T_2)_{\text{free spin}} \text{ at } 0.4^\circ\text{K.}$$

The calculated line width is not strictly constant from room temperature to liquid He temperature, but shows a maximum near $2\sim 3^\circ\text{K}$.

For $H_0 \parallel K_2$ or K_3 ,

$$1/T_2 \sim 0.1(1/T_2)_{\text{free spin}}$$

for room temp. $\sim$ liq. He temp.,

$$\sim 0.003(1/T_2)_{\text{free spin}} \text{ at } 0.4^\circ\text{K.}$$

The line width decreases only slightly as we go from room temperature down to liquid helium temperatures. If we take $(\Delta H)_{\text{free}} \sim 400$ gauss for Ni^{2+} in this salt, the width of Mn^{2+} becomes of the order of $100\sim 40$ gauss for this temperature range. This result is consistent with experiment so long as the order of magnitude is concerned. Its temperature dependence should become remarkable only below 1°K . As the narrowing condition, $(\partial S)_a \ll S$, is not so well satisfied for Ni^{2+} as for Fe^{2+} spins, the value of the line width may become a little larger than the above estimation. The magnetic field dependence may be somewhat between $\sqrt{H_0^2 + H_1^2}$ (no narrowing) and $H_0^2 + H_1^2$ (extreme narrowing). There is no available data of the field dependence of the line width.

If we assume $f(t) = \exp(-\frac{1}{2}\omega_e^2 t^2)$, we shall be justified to estimate the relaxation time T_1 from

$$T_1 \sim T_2 \exp(\frac{1}{2}\omega_0^2/\omega_e^2).$$

Since this quantity depends strongly on ω_e , accurate value of ω_e is necessary in order to obtain a reliable result. T_1 reaches its minimum (same order of magnitude as T_2) when $\omega_0 \sim \omega_e$, and it becomes longer very rapidly when H_0 is further increased. If we take, for the time being, $H_0=3000$ gauss, $\omega_0/\omega_e \sim 6$, the following results are obtained:

for Mn^{2+} in $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$,

$$\begin{aligned} H_0 \perp K_2 \quad T_1 &\gtrsim 1 \text{ sec. at } 4^\circ\text{K,} \\ &\gtrsim 10 \text{ sec. at } 2^\circ\text{K,} \end{aligned}$$

$$\begin{aligned} H_0 \parallel K_2 \quad T_1 &\sim 10^3 \text{ sec. at } 4^\circ\text{K,} \\ &\sim 10^4 \text{ sec. at } 2^\circ\text{K.} \end{aligned}$$

for Mn^{2+} in $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$,

$$H_0 \parallel K_1 \quad T_1 \sim 0.03 \text{ sec.}$$

for room temp. $\sim$ liq. He temp.

$$H_0 \perp K_1 \quad T_1 \sim 0.1 \text{ sec.}$$

for room temp. $\sim$ liq. He temp.

These are only rough order estimations, but it is certain that this mechanism is more important in Ni^{2+} salts than in Fe^{2+} salts.

(iii) $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$.

Magnetic field dependence of the line width at room temperature was measured by I. Hayashi*. According to it the line width increases as the magnetic field increases and the magnitude of the field dependent part of the line width is much larger than in $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and is of the same order of magnitude as in $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, in qualitative agreement with the expectation from our theory.

The fine structure constants of this salt were determined by Ôno from paramagnetic resonance experiment¹¹). They are

$$D=3.56 \text{ cm}^{-1}, \quad E=1.50 \text{ cm}^{-1}. \quad (6.5)$$

The crystal structure is found in reference 11).

The whole considerations on T_1 in this section are valid when the heat capacity of Fe^{2+} (or Ni^{2+}) spin system is much larger than that of Mn^{2+} spins. Even if this condition is not so well satisfied, our considerations remain at least qualitatively valid when the heat contact of Fe^{2+} spin system with the lattice is very good. Some results of paramagnetic relaxation experiments by Haseda⁹) may be interpreted in connection with the above-mentioned mechanism. Relaxation rate due to this is additive to that due to the spin-orbit coupling (Van Vleck mechanism).

§ 7. Concluding Remarks

Our study presented above is of almost purely theoretical character based on a spin Hamiltonian. Though some experimental results of electron spin resonances seem to support our theory, more experimental studies are needed to confirm it.

Disappearance of the proton resonance line

* I. Hayashi, unpublished data. We should like to thank Dr. I. Hayashi for allowing us to quote his data prior to publication.

in some Ni salts at low temperatures reported by Kim and Sugawara⁴⁾ is not understood from our theory, though the very rapid increase of T_1 at low temperatures may have some relation to those phenomena.

We expect further experimental studies on both nuclear and electron spin resonances.

In conclusion the writers would like to thank Dr. T. Sugawara and Mr. P. H. Kim for providing them with a stimulus to the problem. They thank also Prof. R. Kubo and Dr. M. Shimizu for their kind interest and discussions.

Nuclear Magnetic Resonance of Transition Elements in Paramagnetic Salts

By Tôru MORIYA

Department of Physics, Tokyo Metropolitan University

(Received August 2, 1958)

Nuclear magnetic resonance of transition elements in paramagnetic salts under two situations is studied theoretically. One is the case where the magnetic ions have no Kramers degeneracy and their spin degeneracy is completely lifted by the combined action of the spin-orbit coupling and the crystalline electric field. Another is the case of the ideal paramagnetic substances under a strong magnetic field and at low temperatures. The resonance field (or frequency) shift, the relaxation times T_1 and T_2 due to hyperfine interaction and the indirect nuclear spin coupling via electron spins are calculated. The results show that the nuclear resonance of transition elements in paramagnetic salts is expected to be observable under favorable conditions.

§ 1. Introduction

Nuclear magnetic resonance of transition elements has never been observed except when the ions are diamagnetic such as cobalt in complex salts. The reason for this is in paramagnetic substances considered to be due to very large fluctuating magnetic field at the nucleus produced by the electron spin through hyperfine interaction, which makes the nuclear

resonance line width so large and T_1 so short as to prevent the observation of the resonance¹⁾. In antiferromagnetic state this fluctuating magnetic field decreases rapidly as temperature is lowered¹⁾, while there grow very large indirect couplings among the nuclei via spin waves^{2),3)} which again make the observation of the nuclear resonance difficult.

In the present article we shall give a theore-

tical treatment of the nuclear magnetic resonance of transition elements in paramagnetic salts for two cases. One is the case which was our concern in the preceding article^{4)*}, i.e., the case where the magnetic ions have no Kramers degeneracy and their spin degeneracy is completely lifted by a crystalline electric field. Another is the case where the paramagnetic ordering occurs in a usual Zeeman system under strong magnetic field at low temperatures.

In both of these cases nuclear resonance is expected to be observable provided the energy level separation between the ground state and the lowest excited state is large compared with the spin-spin interaction energy as well as kT , though the frequency will be shifted quite remarkably. These conditions mean that there is a considerable amount of spin ordering and thus a decrease of the fluctuating magnetic field at the nucleus produced by the electron spins. There are, however, a competing effect of indirect nuclear spin coupling via electron spins which becomes larger as temperature is lowered and is unfavorable for the observation of nuclear resonance. If the above stated conditions are satisfied this indirect nuclear spin coupling also will not be very large as will be shown in the following sections.

We shall here treat the problems of nuclear resonance field shift, relaxation rate by hyperfine interaction, and indirect coupling between nuclear spins in two cases stated above.

§ 2. The Case where a Crystalline Field removes the Spin Degeneracy Completely

(I) Resonance field shift

The general formulas for the shift, T_1 and T_2 in § 2 of I are of course applicable here. The coupling constant between the nuclear spin and the electron spins are taken as

$$\mathcal{O}_{ij} = (\gamma_e \gamma_N \hbar^2)^{-1} [A_i \delta_{ij} + B_{ij}(1 - \delta_{ij})], \quad (2.1)$$

where A_i is the hyperfine coupling tensor for the i -th ion, B_{ij} comes from the dipole-dipole interaction between the i -th nuclear spin and

the j -th electron spin. Inserting (2.1) into (2.9) of I, we get the following expression for the total magnetic field at the i -th nucleus:

$$\mathbf{H}_i = (1 + \sigma_i) \cdot \mathbf{H}_0, \quad (2.2)$$

$$\sigma_i = (1/\gamma_N \hbar \mu_B) [A_i \cdot \mathbf{g}_i^{-1} \cdot \bar{\chi}_i + \sum_{(j \neq i)} B_{ij} \cdot \mathbf{g}_j^{-1} \cdot \bar{\chi}_j], \quad (2.3)$$

where $\bar{\chi}_i$ denotes the magnetic susceptibility tensor (per ion) for the i -th ion defined by $\mu_B \mathbf{g}_i \langle S_i \rangle = \bar{\chi}_i \cdot \mathbf{H}_0^{**}$.

Usually A is much larger than B and the shift of the resonance field is principally determined by the hyperfine coupling. Its order of magnitude is estimated as follows: we have $A/(\gamma_N \times 10^{-4}) \sim 10^{-2} \text{ cm}^{-1} \sim 2 \times 10^{-18} \text{ cgs}$ for V^{2+} , Cr^{3+} and Mn^{2+5} , so that

$$\sigma = 10^{25} \bar{\chi} \sim 20 \bar{\chi}_M \text{ (per mole)}. \quad (2.4)$$

χ takes a constant value at low temperatures whose order of magnitude is $\chi \sim 2g^2 \mu_B^2 / 4 \sim 4 \times 10^{-24} / 4$ (in cm^{-1}) for $S=1$, 4 being the initial splitting. For example, if we take $4 \sim 2 \text{ cm}^{-1}$ we get $\sigma \sim 20$. Usually we expect very large shift.

R. J. Elliott considered a similar problem for a rare earth ion $\text{Eu}^{3+6)}$. In this case σ becomes negative i.e. the shift is diamagnetic.

(II) Relaxation times

The nuclear relaxation times T_1 and T_2 due to the hyperfine coupling are calculated with the use of the formulas in §§ 2, 3, and 5 of I. The results are

$$1/T_1 = \frac{(\pi/2)^{1/2}}{\hbar^2 \omega_e} \sum_{\nu, \nu'} (\delta_{\nu\nu'} A_{\nu}^2 - \alpha_{\nu} \alpha_{\nu'} A_{\nu} A_{\nu'}) \times kT (\chi_T - \chi_{is})_{\nu\nu'} / g_{\nu} g_{\nu'} \mu_B^2, \quad (2.5)$$

$$1/T_2 = \frac{(\pi/2)^{1/2}}{2\hbar^2 \omega_e} \sum_{\nu, \nu'} (\delta_{\nu\nu'} A_{\nu}^2 + \alpha_{\nu} \alpha_{\nu'} A_{\nu} A_{\nu'}) \times kT (\chi_T - \chi_{is})_{\nu\nu'} / g_{\nu} g_{\nu'} \mu_B^2, \quad (2.6)$$

Where we took the principal axes of the hyperfine coupling tensor as x , y and z axes. $\alpha_1, \alpha_2, \alpha_3$ are the direction cosines of the total magnetic field, $\mathbf{H} = (1 + \sigma) \cdot \mathbf{H}_0$, at the nucleus, χ_T, χ_{is} the isothermal and isolated susceptibilities per ion. Calculations of χ_T and χ_{is} for $S=1, 2$ are found in I. We assumed a Gaussian shape for the frequency distribution of the electron spin fluctuations, i.e. we took

** The susceptibility defined here is not always a usual one. When H_0 is large $\bar{\chi}$ differs from the differential susceptibility, $\chi = -(\partial^2 F / \partial H^2)$, F being the free energy.

* Referred to below as I. In that article we presented a theory of magnetic resonance of nuclear spins and electron spins of impurity ions in those paramagnetic salts where the spin degeneracy of an ion is completely lifted by the combined action of the spin-orbit coupling and the crystalline electric field.

the form $f(t) = e^{-(1/2)\omega_e^2 t^2}$ for the decay of the time correlation functions of the electron spin fluctuations. $\hbar\omega_e$ is of the order of magnitude of electronic spin-spin interaction. As was seen in I, T_1 and T_2 increase rapidly (exponentially) as temperature is lowered at low temperatures.

(III) Indirect coupling

Indirect couplings among the nuclear spins are derived by the second order perturbation calculation taking $\mathcal{H}_e$, the Hamiltonian of the electron spin system, as an unperturbed Hamiltonian and $\mathcal{H}_{Ne}$, the interaction between the nuclear spins and the electron spins, as a perturbing Hamiltonian. It is, however, usually very difficult to obtain the eigenstates of the electron spin system, the eigenstates of $\mathcal{H}_e$. In ferro and antiferromagnetic substances spin waves represent the eigen states in good approximation at low temperatures. In the present case the perturbation method is applicable to calculate the approximate eigenstates of the electron spin system when the energy level separations of the spin levels are large compared to the spin-spin interaction energy. The couplings arising from the lower order approximation to the electron spin system are concerned only with a few electron spins.

The indirect coupling between the nuclear spin of a magnetic ion and that of a non-magnetic ion is principally due to magnetic antishielding effect, where the electron spin of only one ion takes part in. On the other hand, the indirect coupling between two nuclear spins of magnetic ions comes mainly by way of the hyperfine couplings in the two ions; the electron spins of the two ions take part in this mechanism. We shall below deal with these two mechanisms.

We want now to obtain an expression for the indirect nuclear spin coupling at an arbitrary temperature. Our approximate eigenstates are localized ones concerned with only one or two electron spins. In calculating the indirect coupling between two nuclear spins it will be justified to take an average over all the electron spin states, since the transitions among the localized spin states due to the spin-spin interactions are so rapid as to satisfy

$$\hbar^{-1}A\omega_0\tau^2 \ll 1, \quad (2.7)$$

where A is the hyperfine coupling constant,

ω_0 the nuclear Larmor frequency and τ the electron spin relaxation time due to spin-spin interactions. This condition means that the motion of the electron spins is so rapid that they show their average values at any instant of the nuclear spin motion. Denoting the eigenfunctions and the eigenvalues of the electron spin system by ϕ_α and E_α etc., we may write

$$\mathcal{H}^{\text{eff}} = \sum_{\alpha > \beta} \frac{f_\alpha - f_\beta}{E_\alpha - E_\beta} (\alpha | \mathcal{H}' | \beta) (\beta | \mathcal{H}' | \alpha) \quad (2.8)$$

as the effective Hamiltonian for the indirect nuclear spin coupling, where

$$f_\alpha = \exp(-E_\alpha/kT) / \sum_\beta \exp(-E_\beta/kT),$$

$\mathcal{H}'$ represents the interaction between the electron spins and the nuclear spins including hyperfine as well as the dipole-dipole interactions.

It is of interest to remark here that the above expression is not accurate when the spin-lattice relaxation time τ_1 of the electron spins is rapid. When τ_1 satisfies

$$\hbar^{-1}A\omega_0\tau_1^2 \ll 1, \quad (2.9)$$

we have rather to calculate the free energy of the system regarding the nuclear spin operators as parameters. From the second order terms of the perturbation calculation of the free energy the effective Hamiltonian for the indirect nuclear spin coupling results. This may be formulated as follows:

$$F = F_0 + \langle \mathcal{H}' \rangle + \frac{1}{2} \left\{ \langle \mathcal{H}'^2 \rangle / kT - \int_0^{1/kT} d\lambda \langle \mathcal{H}'(\lambda) \mathcal{H}' \rangle \right\} + \dots, \quad (2.10)$$

where

$$\mathcal{H}'(\lambda) = \exp(-\lambda \mathcal{H}_e) \mathcal{H}' \exp(\lambda \mathcal{H}_e).$$

F is the free energy, F_0 that of the electron spin system neglecting the nuclear spin system, i.e.

$$\exp(-F_0/kT) = \text{Tr} \exp(-\mathcal{H}_e/kT)$$

where $\mathcal{H}_e$ is the Hamiltonian of the electron spin system including the spin-spin interactions, $\langle \rangle$ means to take thermal average,

$\langle Q \rangle = \text{Tr} Q \exp(-\mathcal{H}_e/kT) / \text{Tr} \exp(-\mathcal{H}_e/kT)$, and $\mathcal{H}'$ denotes the Hamiltonian of the interaction between the nuclear spins and the electron spins. The third term is to be used as the effective Hamiltonian of the indirect nuclear spin coupling.

These two formulas are in general different though it is equivalent when $\mathcal{H}'$ has no diagonal element. It is to be determined according to the case which of these two formulas should be used. In both cases, as one sees easily, the antishielding effect arises from those terms bilinear with respect to the hyperfine and the dipole-dipole interactions (and those quadratic in the dipole-dipole interaction) though we derive it below in an instinctive but equivalent way.

(a) *Antishielding effect*

In a magnetic ion the nuclear spin polarizes the electron spin by the hyperfine coupling between them. The polarized moment of the electron spin follows the nuclear spin as it processes, i.e. the induced moment may be written as

$$\chi_i \cdot g_i^{-1} \cdot A_i \cdot I_i / \mu_B, \quad (2.11)$$

where χ_i is the susceptibility tensor of the i -th ion. When the spin-lattice relaxation time is not short and does not satisfy (2.9) χ_i should be an isolated susceptibility, while when (2.9) is satisfied the state of affairs becomes much difficult though to take isothermal susceptibility for χ_i may represent an extreme approximation. The latter approximation will be justified when the spin-lattice relaxation time is shorter than the spin-spin relaxation time. However, the above two alternatives are not much different when the Zeeman energy is not too large; isothermal and isolated susceptibilities agree when the external field is negligible compared to the initial splittings of the spin levels.

The induced magnetic moment given by (2.11) interacts with the nuclear spins of the surrounding ions, resulting in an effective coupling between the nuclear spins. The effective couplings among the nuclear spins thus produced can be written as follows:

$$\mathcal{H}^{\text{eff}} = \hbar^2 \sum_{i>j} \gamma_i \gamma_j r_{ij}^{-3} [I_i \cdot (1 - 3t_{ij}t_{ij}) \cdot \sigma_j I_j + I_j \cdot (1 - 3t_{ij}t_{ij}) \cdot \sigma_i \cdot I_i], \quad (2.12)$$

where

$$\left. \begin{aligned} \psi_{mm} &= \varphi_m(i) \varphi_m(j), \\ \psi_{mm'}^{\alpha} &= \frac{1}{\sqrt{2}} \{ \varphi_m(i) \varphi_{m'}(j) - (-1)^{\alpha} \varphi_{m'}(i) \varphi_m(j) \}. \end{aligned} \right\} \quad (2.14)$$

α takes 1 and 2 and $\varphi_m(i)$ denotes the eigenfunction of one spin Hamiltonian $\mathcal{H}_i$ belonging to the eigenvalue E_m . The energy eigenvalues corresponding to the eigenfunctions given by

$$\sigma_i = A_i \cdot g_i^{-1} \cdot \chi_i / \gamma_i \hbar \mu_B, \quad (2.13)^*$$

γ_i and γ_j being the gyromagnetic ratios of the i -th and the j -th nuclear spins.

This coupling is σ -times as large as the direct spin-spin interaction. From the estimation of (I), one sees that this coupling can, in some cases at low temperatures, be more than ten times as large as the direct dipole-dipole interaction.

We shall remark here that this effect may be regarded as a magnetic counterpart of Sternheimer's antishielding correction to the nuclear quadrupole interaction⁷⁾.

(b) *Indirect coupling between two nuclei of magnetic ions through hyperfine couplings*

The approximate eigenstates of the electron spin system are obtained by perturbation calculation. If we terminate the series at the first order term of the eigenfunction, we get the indirect coupling concerned with two electron. The convergence of the perturbation series will be good for the coupling between neighboring spins and when the electron spin-spin interaction is of short range character. The calculation is usually rather troublesome though straightforward. We shall here pick up a representative term in which a kind of configuration mixing is taken into account.

In the representation in which $\mathcal{H}_{e0}$ is diagonal, $\mathcal{H}'_e$ can be divided into two part, i.e. secular or energy-diagonal terms and non-secular terms. Here we take into account only the secular terms in which, as is seen below, those representing the simultaneous flippings of two spins are important. The contribution of the non-secular terms of the indirect nuclear spin coupling is of the same order of magnitude as that of the secular terms.

Let us consider the coupling between the i -th and the j -th nuclear spins. We may take the electron spin eigenfunctions concerned with the i -th and the j -th ions. They are

* It should be noticed that this expression is, in general, different from (2-3).

(2.4) are

$$\left. \begin{aligned} E_{mm} &= 2E_m + U_{ij}(mm), \\ E_{mm'}^o &= E_m + E_{m'} + U_{ij}(mm') - (-1)^a W_{ij}(mm'), \quad (m \neq m') \end{aligned} \right\} \quad (2.15)$$

where

$$\left. \begin{aligned} U_{ij}(m, m') &= (\varphi_m(i) \varphi_{m'}(j) | \mathcal{H}_{ij} | \varphi_m(i) \varphi_{m'}(j)), \\ W_{ij}(m, m') &= (\varphi_m(i) \varphi_{m'}(j) | \mathcal{H}_{ij} | \varphi_{m'}(i) \varphi_m(j)). \end{aligned} \right\} \quad (2.16)$$

Taking the hyperfine coupling,

$$\mathcal{H}' = \sum_i A_{iv} I_{iv} S_{iv} + \sum_j A_{jv} I_{jv} S_{jv}, \quad (2.17)$$

as a perturbing Hamiltonian, we get the effective Hamiltonian for the indirect coupling between the i -th and the j -th nuclear spins. The result is

$$\left. \begin{aligned} \mathcal{H}_{ij}^{\text{eff}} &= I_i \cdot \mathcal{A}_{ij} \cdot I_j, \\ \mathcal{A}_{ij} &= \sum_{m>n} \frac{W_{ij}(m, n)}{(E_m - E_n)^2} (f_m - f_n)^2 \cdot A_i \cdot \{ (m|S|n)(n|S|m) + (n|S|m)(m|S|n) \} \cdot A_j, \end{aligned} \right\} \quad (2.18)$$

where

$$f_m = \exp(-E_m/kT) / \sum_n \exp(-E_n/kT).$$

This coupling has a nearly constant value at very low temperatures where $kT \ll E_1 - E_0$, E_0 and E_1 being the energies of the ground and the excited states and decreases as temperature rises. At high temperatures it vanishes like $1/T^2$.

The magnitude of this coupling at low temperatures is estimated as

$$\sim \left(\frac{A}{\Delta E} \right)^2 \cdot \left(\frac{r_e}{r_N} \right)^2 \cdot \mathcal{H}_d, \quad (2.19)$$

where $\mathcal{H}_d$ denotes the direct dipole-dipole interaction between the nuclear spins. Estimating $(A/r_N) \sim 10^{-6} \text{ cm}^{-1}$, $r_e = 1.76 \times 10^7$, we see that the indirect coupling is about $\sim 3 \times 10 / \Delta E^2$ (in cm^{-1}) times as large as direct dipole-dipole interaction. This coupling will be more important than the effect of antishielding as regards the indirect coupling between two magnetic ions. When the concentration of magnetic ion is high the effect of this coupling is of major importance. On the other hand when this concentration is low such as in hydrated salts the antishielding effect may predominate.

§ 3. Paramagnetic Ordering and Nuclear Resonance

The problems treated in the preceding sections were rather special ones because the absence of the Kramers degeneracy and comparatively large initial splittings of the spin levels were the essential conditions. In this section our consideration will be extended to the ideal paramagnetic substances under a strong external magnetic field and at low temperatures. When the Zeeman energy is large compared to the spin-spin interaction as well as kT , the fluctuation of spins decreases rapidly as temperature is lowered and as the external field becomes stronger. The observation of the nuclear resonance will become easier since T_1 and T_2 will become longer as H/T increases. However, there is again an unfavorable effect of indirect coupling as in the case treated in the preceding section. There is, of course a large shift of the nuclear resonance frequency. We shall calculate below the shift, the relaxation time due to the hyperfine coupling and the indirect nuclear spin coupling. The Zeeman energy is assumed to be much larger than the spin-spin interaction energy.

(I) *Resonance field shift*

The direction of the external magnetic field is taken as z -axis. Then the total magnetic field at the i -th nuclear spins is written as

$$H_{iv} = H\alpha_v = H_0 + g\mu_B \sum_j \Phi_{ij} \nu^3 \langle S_{jz} \rangle, \quad (3.1)$$

$$\langle S_{jz} \rangle = -SB_S(g\mu_B H_0/kT) \quad (3.2)$$

where $B_S(x)$ denotes a Brillouin function:

$$B_S(x) = \frac{2S+1}{2S} \coth\left(\frac{2S+1}{2S} x\right) - \frac{1}{2S} \coth(x/2S).$$

At low temperatures the shift amounts to the same order of magnitude as in ferro and anti-ferromagnetic substances.

(II) *Relaxation time due to hyperfine coupling*

The skeleton of the frequency spectrum of the spin fluctuation is as follows:

$$\left. \begin{aligned} \langle \{\delta S_x^0(t) \delta S_x\} \rangle &= \langle S_x^2 \rangle = \langle S_x \rangle^2, \\ \langle \{\delta S_x^0(t) \delta S_x\} \rangle &= \langle \{\delta S_y^0(t) \delta S_y\} \rangle = -\frac{1}{2} \coth(z/2) \langle S_z \rangle \cos(\omega_s t), \\ \langle \{\delta S_x^0(t) \delta S_y\} \rangle &= -\langle \{\delta S_y^0(t) \delta S_x\} \rangle = \frac{1}{2} \coth(z/2) \langle S_z \rangle \sin(\omega_s t), \\ \langle \{\delta S_x^0(t) \delta S_z\} \rangle &= \langle \{\delta S_y^0(t) \delta S_z\} \rangle = \langle \{\delta S_z^0(t) \delta S_x\} \rangle = \langle \{\delta S_z^0(t) \delta S_y\} \rangle = 0. \end{aligned} \right\} \quad (3.3)$$

where $S^0(t)$ is defined by $S^0(t) = \exp(it\mathcal{H}_{e0}/\hbar) S \exp(-it\mathcal{H}_{e0}/\hbar)$, $\mathcal{H}_{e0}$ denoting the Zeeman energy, $\langle S_z \rangle$ is given by (3.2) and $\langle S_x^2 \rangle$ is given as follows:

$$\langle \delta S_x^2 \rangle = \langle S_x^2 \rangle - \langle S_x \rangle^2 = -(\partial/\partial z) \langle S_z \rangle = \frac{1}{4} \operatorname{cosech}^2(z/2) - (S + \frac{1}{2}) \operatorname{cosech}^2(S + \frac{1}{2})z, \quad (3.4)$$

where

$$z = g\mu_B H_0/kT, \quad \omega_s = g\mu_B H_0/\hbar. \quad (3.5)$$

Fig. 1. $\langle \delta S_x^2 \rangle$ as a function of $z = g\mu_B H_0/kT$ calculated from (3.4).

As one sees easily, when the Zeeman energy is much larger than the spin-spin interaction energy, only the z -component of the spin fluctuations is effective to the nuclear relaxation because the x and y components are mainly of high frequency: their low frequency components are negligible. Finally we get the following expressions for the nuclear relaxation times:

$$\begin{aligned} 1/T_2 &= (\pi/2)^{1/2} (\gamma_N^2 g^2 \mu_B^2 / \omega_e) \sum_j \sum_{\nu, \nu'} [\alpha_\nu \alpha_{\nu'} \\ &\quad + \frac{1}{2} (\delta_{\nu\nu'} - \alpha_\nu \alpha_{\nu'}) e^{-\omega_0^2/2\omega_e^2} \Phi_{ij} \nu^3 \Phi_{ij} \nu'^3 \langle \delta S_{iz}^2 \rangle], \end{aligned} \quad (3.6)$$

$$\begin{aligned} 1/T_1 &= (\pi/2)^{1/2} (\gamma_N^2 g^2 \mu_B^2 / \omega_e) \sum_j \sum_{\nu, \nu'} (\delta_{\nu\nu'} - \alpha_\nu \alpha_{\nu'}) \\ &\quad \times e^{-\omega_0^2/2\omega_e^2} \Phi_{ij} \nu^3 \Phi_{ij} \nu'^3 \langle \delta S_{jz}^2 \rangle, \end{aligned} \quad (3.7)$$

where $\langle \delta S_x^2 \rangle$ is given by (3.4) and is shown in Fig. 1 as a function of H_0/T .

(III) *Isothermal and isolated (adiabatic) susceptibilities*

Before entering the discussion on the indirect couplings we shall calculate the magnetic susceptibilities. As was stated in I, isolated and adiabatic susceptibilities mean the

adiabatic susceptibilities in the Ehrenfest sense and in the thermodynamical sense respectively. Isothermal one is the usual one measured keeping thermal equilibrium of the spin system with the heat reservoir. In another words the isolated susceptibility comes only from the effect of magnetic polarization of the system while the isothermal one comes not only from the polarization effect but also from the effect of redistribution of the populations in the spin levels. As is easily seen the external field along the z -axis cannot polarize the system except due to the small effect of dipole-dipole interaction. Therefore we have

$$\left. \begin{aligned} (\chi_{is})_z &= \left\langle \frac{\partial^2 E}{\partial H_z^2} \right\rangle = 0, \\ (\chi_T)_z &= (\chi_{is})_z + \frac{1}{kT} \left(\left\langle \left(\frac{\partial E}{\partial H_z} \right)^2 \right\rangle - \left\langle \frac{\partial E}{\partial H_z} \right\rangle^2 \right) = g^2 \mu_B^2 (\langle S_z^2 \rangle - \langle S_z \rangle^2) / kT, \\ (\chi_s)_z &= (\chi_T)_z - \left(\left\langle E \frac{\partial E}{\partial H_z} \right\rangle - \langle E \rangle \left\langle \frac{\partial E}{\partial H_z} \right\rangle \right)^2 / kT (\langle E^2 \rangle - \langle E \rangle^2) = 0. \end{aligned} \right\} \quad (3.8)$$

Similarly

$$(\chi_{is})_x = (\chi_s)_x = (\chi_T)_x = -g \mu_B \langle S_z \rangle / H_0. \quad (3.9)$$

(IV) Indirect coupling

The indirect coupling in this case can be treated in the same way as in the preceding section. We shall here give more precise expressions than in the preceding section, because the result is simpler in this case.

(a) Antishielding effect

When the spin-lattice relaxation time of the electron spin is not too short, the electronic moments induced by nuclear spins are coming only from the polarization effect. We should then use the isolated susceptibility in the expression (2.13). As was seen in the preceding paragraph, the only nonvanishing components of the isolated susceptibility are

$$(\chi_{is})_{xx} = (\chi_{is})_{yy} = -g \mu_B \langle S_z \rangle / H_0.$$

The nuclear spin coupling by antishielding effect can be written as follows assuming the isotropic hyperfine interactions:

$$\begin{aligned} \mathcal{H}^{\text{eff}} = & -(\hbar A \langle S_z \rangle / H_0) \left[\sum_{i,j} \gamma_i \gamma_j r_{ij}^{-3} \{ (1 - \frac{3}{2} t_{ij}^+ t_{ij}^-) (I_{i+} I_{j-} + I_{i-} I_{j+}) - \frac{3}{2} t_{ij}^z t_{ij}^z (I_{i+} I_{j+} + I_{j-} I_{i+}) \right. \\ & \left. - \frac{3}{2} t_{ij}^z t_{ij}^+ (I_{i+} I_{j-} + I_{j-} I_{i-}) + \frac{3}{2} (t_{ij}^-)^2 I_{i+} I_{j+} - \frac{3}{2} (t_{ij}^+)^2 I_{i-} I_{j-} \right] \\ & + \sum_{i,l} \gamma_i \gamma_l r_{il}^{-3} \{ \frac{1}{2} (1 - \frac{3}{2} t_{il}^+ t_{il}^-) (I_{i+} I_{l-} + I_{l-} I_{i+}) - \frac{3}{2} t_{il}^z t_{il}^z I_{i+} I_{l+} \\ & \left. - \frac{3}{2} t_{il}^z t_{il}^+ I_{i+} I_{l-} - \frac{3}{2} (t_{il}^-)^2 I_{l+} I_{i+} - \frac{3}{2} (t_{il}^+)^2 I_{l-} I_{i-} \right\}, \end{aligned} \quad (3.10)$$

where i and j specify the magnetic ions and l the nonmagnetic ions. A denotes the isotropic hyperfine coupling constant, γ_l the gyromagnetic ratio of the l -th nuclear spin and $t_{ij} = \mathbf{r}_{ij} / r_{ij}$.

In the expression (3.10) the first term is the only secular term. The coupling between different kinds of nuclear spins has in general no secular terms because of their different gyromagnetic ratios. Therefore, the indirect nuclear spin coupling between the magnetic ion and the different kind of ions such as protons in the water molecules will not make any contribution to the line width of the nuclear resonance of the magnetic ions, in contrast with the preceding section. On the other hand this type of indirect nuclear spin coupling between the same kind of magnetic ions proves to contribute to the line width but to the smaller extent than the contribution stated in the following paragraph. This was also the case in the preceding section.

(b) Indirect coupling between two nuclei of magnetic ions through hyperfine interactions

Hamiltonian of the electron spin system is expressed as follows:

$$\left. \begin{aligned} \mathcal{H}_e &= \sum_i \mathcal{H}_{i^{(e)}} + \sum_{i>j} \mathcal{H}_{ij^{(e)}}, & \mathcal{H}_{i^{(e)}} &= g\mu_B H_0 S_{iz}, \\ \mathcal{H}_{ij^{(e)}} &= 4A_{ij}S_{iz}S_{jz} + B_{ij}(S_{i+}S_{j-} + S_{i-}S_{j+}) + C_{ij}(S_{iz}S_{j+} + S_{i+}S_{jz}) \\ &\quad + D_{ij}(S_{iz}S_{j-} + S_{i-}S_{jz}) + E_{ij}S_{i+}S_{j+} + F_{ij}S_{i-}S_{j-}, \end{aligned} \right\} \quad (3.11)$$

where A_{ij} , B_{ij} , ... are given by

$$\left. \begin{aligned} A_{ij} &= \frac{1}{4}\{J_{ij} + K_{ij}[1 - 3(t_{ij}^x)^2]\}, & B_{ij} &= \frac{1}{4}\{J_{ij}K_{ij}(1 - 3t_{ij}^+t_{ij}^-/2)\}, \\ C_{ij} &= -3K_{ij}t_{ij}^xt_{ij}^-/2, & D_{ij} &= -3K_{ij}t_{ij}^xt_{ij}^+/2, \\ E_{ij} &= -3K_{ij}(t_{ij}^-)^2/4, & F_{ij} &= -3K_{ij}(t_{ij}^+)^2/4, \end{aligned} \right\} \quad (3.12)$$

J_{ij} being -2 times the exchange integral between i -th and j -th ions and $K_{ij} = g^2\mu_B^2/r_{ij}^3$. The interaction between the electron and the nuclear spins are expressed as

$$\mathcal{H}_{Ne} = \sum_i (A_{1i}I_{ix}S_{iz} + A_{2i}I_{iy}S_{iz} + A_{3i}I_{iz}S_{iz}). \quad (3.13)$$

The calculation of the indirect coupling is carried out in the same way as in the preceding section. We shall give here only the result:

$$\begin{aligned} \mathcal{H}_{ij}^{\text{eff}} &= \tanh^2(g\mu_B H_0/kT)/(4g\mu_B H_0)^2 \{ (A_+^2 + A_-^2)B_{ij} + A_+A_-(E_{ij} + E_{ij}) \} (I_{i+}I_{i-} + I_{i-}I_{i+}) \\ &\quad + \{ 2A_+A_-B_{ij} + A_+^2E_{ij} + A_-^2F_{ij} \} I_{i+}I_{j+} + \{ 2A_+A_-B_{ij} + A_-^2E_{ij} + A_+^2F_{ij} \} I_{i-}I_{j-} \\ &\quad - (A_+C_{ij} + A_-D_{ij})A_3(I_{iz}I_{j+} + I_{jz}I_{i+}) - (A_-C_{ij} + A_+D_{ij})A_3(I_{iz}I_{j-} + I_{jz}I_{i-}), \end{aligned} \quad (3.14)$$

where $A_{\pm} = A_1 \pm A_2$. When the hyperfine coupling is isotropic this reduces itself simply to

$$\begin{aligned} \mathcal{H}_{ij}^{\text{eff}} &= A^2 \tanh^2(g\mu_B H_0/kT)/(2g\mu_B H_0)^2 [B_{ij}(I_{i+}I_{j-} + I_{i-}I_{j+}) \\ &\quad - \frac{1}{2}C_{ij}(I_{iz}I_{j+} + I_{jz}I_{i+}) - \frac{1}{2}D_{ij}(I_{iz}I_{j-} + I_{jz}I_{i-}) + E_{ij}I_{i+}I_{j+} + F_{ij}I_{i-}I_{j-}]. \end{aligned} \quad (3.15)$$

In the above expression only the first term can contribute to the line width. Its order of magnitude at low temperatures is

$$A^2 B_{ij}/(2g\mu_B H_0)^2 \sim 10^{10} \mathcal{H}_a/H_0^2, \quad (3.16)$$

where $\mathcal{H}_a$ denotes the direct dipole-dipole interaction between nuclear spins. When $H_0 \simeq 10000$ gauss, the indirect coupling is about 100 times as large as the direct dipole-dipole interaction. However, this does not necessarily mean that the observation of the nuclear resonance is difficult. In the usual hydrated salts, the magnetic ions are located keeping rather long distances with each other and the actual magnitude of their indirect coupling is not necessarily so large as to prevent the observation of nuclear resonance.

§ 4. Concluding Remarks

From the results of the preceding sections we see that it seems to be possible to observe nuclear magnetic resonance of transition elements in some paramagnetic salts under favorable conditions.

The first case treated in § 2 is a rather special one. When the initial splitting is suffi-

ciently large (far larger than spin-spin interaction as well as kT) we expect that the relaxation times T_1 and T_2 by hyperfine interaction are not very short and at the same time the indirect nuclear spin couplings will not be large, thus favoring the observation of the nuclear resonance of transition elements. We expect these situations in some salts of Mn^{3+} , Cr^{2+} and V^{3+} .

In § 3 we dealt with the case of ideal paramagnetic substances, where the nuclear resonance of transition elements is expected to be observable under sufficiently strong magnetic field and at sufficiently low temperatures. The treatment will easily be extended to more general cases where the magnetic ions have Kramers doublets under no external magnetic field and show magnetic anisotropy.

When the resonance is observed we shall be able to add some interesting information to the magnetic properties of paramagnetic ions such as fine and hyperfine structures under the influence of the crystalline electric field, and then some characters of the wavefunctions of the magnetic ions, some informa-

tion on spin-spin interaction in paramagnetic salts, etc.

The writer wishes to thank Prof. R. Kubo and Dr. M. Shimizu for their valuable discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 11, NOVEMBER, 1958

Electroluminescence of Insulated Particles

By Keiji MAEDA

*Matsuda Research Laboratory, Tokyo Shibaura
Electric Co., Kawasaki*

(Received July 25, 1958)

The origin of the local high electric field in the electroluminescence of insulated phosphor particles is considered and attributed to the disturbance of the applied field due to the conductive substance in the insulative phosphor. The distributions of local field are calculated and the dependence of brightness on the applied voltage is discussed. However, the comparison with experiments is impossible because of the complicated structure of the phosphor. Finally, the luminous efficiency of electroluminescent cell is estimated and an agreement is obtained with the observed value.

§ 1. Introduction

The phenomenon that phosphors emit light by the direct action of electric field alone is generally called electroluminescence. The electroluminescence was already found in 1936¹⁾ and an idea of utilizing this as light source appeared about at the beginning of this decade. Although the luminous efficiency of electroluminescence was very low at first, it has been improved to be approximately 10 lm/W up to the present. Therefore, it is not only theoretically but also practically important to understand the mechanisms and characteristics of electroluminescence.

In some experiments of electroluminescence electrodes are in contact with a phosphor layer or with a single crystal while in other experiments there are no electrode contacts. In these two cases the constitution of sample and the method of application of electric field are different. Therefore, these two cases

must be discussed separately, although many investigators do not distinguish them. It is the latter case when electroluminescence is utilized as light source; an insulating dielectric layer, in which phosphor particles are dispersed, is sandwiched between two parallel electrodes and an alternating voltage is applied. As we can suppose from the structure of electroluminescent phosphor, electroluminescence is very complicated phenomenon and we have not a little uncertainties about it, although many investigations have been carried out.²⁾ In this paper, we shall discuss the electroluminescence of insulated particles under the action of alternating electric field.

§ 2. Local High Field

Up to the present, only the small group of ZnS type phosphor is known as efficient powder phosphor for the electroluminescence.

The ordinary phosphor even in this group which is suitable for ultraviolet or cathode-ray excitation does not emit light when it is subjected to an electric field. It becomes electroluminescent if (a) it is covered with metal by evaporation, (b) copper sulfide is deposited on it by washing it with solution of copper salt or (c) the surface is slightly oxidized.^{2),3)} For the preparation of electroluminescent phosphor the copper content in the raw materials is much higher than that for the ordinary phosphor. By removing the surface of the finished phosphor particle chemically, it is known that the copper is concentrated near the surface and the remainder is weakly electroluminescent.⁴⁾ The copper is usually considered to be present as Cu_2S segregated from the ZnS crystal. As Cu_2S and ZnO are known to have good electrical conductivity, the common feature among the above observations is that the presence of conductive substance is essential to make the phosphor electroluminescent.

Further the following facts are important for the discussion of electroluminescence:

(a) The microscopic observation of electroluminescent particle shows that the light is emitted from small spots.⁶⁾

(b) By applying a strong enough magnetic field to quench electroluminescence simultaneously with an electric field, it becomes clear that the electric field strength at the luminous spot is at least ten times larger than the average field in the electroluminescent cell.⁶⁾

(c) The brightness wave of the cell has two peaks and that of each luminous spot has only a single peak in an alternating cycle.⁶⁾

From these results, many workers considered that the field concentration is due to the presence of rectifying barrier between the conductive substance and ZnS . The reality of this model is investigated below.

(1) There is no limitation on the nature of conductive substance. For instance, metals (Cu , Ag), p -type semiconductor (Cu_2S) and n -type semiconductor (ZnO) are used as conductive substance. While, it is reported that various metals including Cu and Ag evaporated on ZnS single crystal do not show noticeable rectifying properties.⁷⁾ Therefore, careful examinations are necessary to assume preferable rectifying barrier in other cases.

(2) The potential distribution in the electroluminescent phosphor particle is drawn schematically in Fig. 1 (a) in the same manner as in the theory of rectification. Differentiating this, we get the field distribution shown in Fig. 1 (b) and, by further differentiation, we get the charge distribution shown in Fig. 1 (c). It should be noted that net charge in the conducting substance is indispensable for the field localization. If the conductor is neutral, i.e., $\rho_A = -\rho_B$ in Fig. 1 (c), the field strength at the surface of ZnS is the same as that in the dielectric. Probably dipole-layer is present at the boundary of two kinds of materials when no electric field

Fig. 1. Local high field due to the rectifying barrier in the insulated phosphor particle.

(a) potential distribution, (b) field distribution, (c) charge distribution.

is applied and the conductor may be charged to some degree due to this dipole layer. When an electric field is applied, provided the conductor is negatively charged, i.e., $|\rho_A| < |\rho_B|$, the field is localized due to the dipole consisting of the charge $\rho_A + \rho_B$ in the conductor and the charge of equal magnitude and opposite sign, ρ_C , in ZnS . The excess charge in ρ_C more than the above decreases the field strength in a part of ZnS distant from the boundary to smaller value than that in the dielectric but has no correlation with the field concentration at the surface of ZnS . In order to increase the local high field proportional to the applied field, the net negative

charge in the conductor $\rho_A + \rho_B$ should be increased in the same proportion. As there is no external charge supply to the conductor and the neutrality of the phosphor particle is maintained, such an increase of space charge cannot but result from a current within the phosphor particle in the opposite direction to the applied field. It is unreasonable. This situation is in contrast to the ordinary rectifying barrier, where electrodes are in contact with semiconductor and the charge in electrodes is supplied externally. Consequently, even if considerable field is present at the boundary between the conductor and ZnS when no electric field is applied, the local field is only the sum of the initial field and the average applied field when an electric field is applied. The observed characteristics cannot be explained by such a local field.

It is concluded, therefore, that the rectifying barrier does not contribute essentially to the electroluminescence of insulated particles. Of course, a possibility that it plays a secondary role cannot be denied.

Zalm presented a model in which the surface dipole varies proportionally with the applied field.³⁾ In his calculation, however, the polarization is neglected. When the polarization is evaluated according to his model, it becomes clear that his model is not self-consistent.

When a uniform electric field is applied on a dielectric, in which conductive material is dispersed, the electric field is disturbed and a very high field is possibly produced. Lehmann observed that the normally nonelectroluminescent phosphors become electroluminescent when they are mechanically mixed with powder of good conductivity, and called this phenomenon contact electroluminescence.⁸⁾ He concluded from the similarity between the ordinary and contact electroluminescence that the former is also due to substances of relatively high conductivity incorporated as small segregations within the insulating phosphor particles. His conclusion is supported by the consideration of electric properties of the constituent materials in the phosphor. Although the resistivities of semiconductors depend greatly on the impurity concentrations and the histories, ZnS is usually a poor conductor⁹⁾ in contrast to ZnO¹⁰⁾ and Cu₂S.¹¹⁾ The reciprocal of the relaxation time of electric field

of ZnS is much smaller and that of ZnO and Cu₂S is much larger than the applied frequencies in the usual experiments of electroluminescence. Therefore, the former can be regarded as insulator and the latter as conductors in the discussion of a.c. electroluminescence. Further, he showed qualitatively that the electric field near the sharp edge of the contact substance is considerably higher than the average electric field across the phosphor crystal. His conclusion is quite reasonable. In the following, the field distribution around the conductive substance will be investigated.

Considering the conditions of preparation of electroluminescent phosphor, the conductive substance is probably a thin layer on the surface of the phosphor particle in many cases. Sometimes it may be a grain incorporated inside the particle. Although the shape of individual conductive substance is quite irregular, we shall assume simple models, i.e., oblate spheroids and prolate spheroids. Probably the edge of conductive substance has a form which is intermediate between the two simple spheroids assumed here. These spheroids are assumed to be embedded in an ideal insulative medium. The boundary between the conductive substance and ZnS may not be a clear cut and, moreover, there may be a dipole layer as discussed above. Hence, the above assumptions must be regarded as a first approximation. Since both ZnS and the dielectric have nearly equal dielectric constant, they are not distinguished in our calculations.

When the conductive spheroid is placed in a uniform electric field E_0 with its major axis parallel to the field, i.e., in the x direction, the potential φ around it is given with ellipsoidal coordinate u

$$\varphi = -E_0 x \left\{ 1 - \frac{\int_u^\infty \frac{du}{(a^2+u)R(u)} \right/ \int_0^\infty \frac{du}{(a^2+u)R(u)} \right\}, \quad (1)$$

where

$$R(u) = \{(a^2+u)(b^2+u)(c^2+u)\}^{1/2}$$

and a , b and c are the axes of spheroid.¹²⁾ For the conductive spheroid around which high field is produced, the major axis is much larger than the minor axis; i.e.,

$$a \gg b > c \quad \text{for oblate spheroid}$$

and

$$a \gg b = c \quad \text{for prolate spheroid.}$$

The field distribution along the extension of the major axis is calculated from Eq. (1) in a first approximation for the oblate spheroid

$$E=\frac{4E_0}{\pi}\left\{\frac{a}{\sqrt{c^2+2ax}}+\frac{x}{c}\right\}\quad\text{for }x\leq c\quad (2)$$

and similary for the prolate spheroid

$$E=\frac{E_0}{\{\log (2a/b)-1\}}\left\{\frac{a^2}{b^2+2ax}+\frac{1}{2}\log \left(1+\frac{2ax}{b^2}\right)\right\}\quad\text{for }x\leq a/2,\quad (3)$$

where x measures the distance from the surface of the spheroid. From these equations, we see that the ratio of the maximum field at the surface to the average field is nearly equal to the ratio of major axis to minor axis for the oblate spheroid and to the square of the axis ratio for the prolate spheroid. Therefore, the local high field exceeding the average by two or more orders of magnitude is conceivable near an edge of actual conductive substance.

For the occurrence of electroluminescence, however, an extension of high field over some distance as well as the high field itself is necessary; i.e., the potential drop in the high field region must be larger than a certain value. For the local high field expressed by Eq. (2) or (3), the extent of the high field cannot be defined unambiguously. We shall compare the field strength at the position, where the first and the second term are equal in Eqs. (2) and (3) respectively, with the maximum field at the surface. Denoting this position by $x=\delta$, we have for the oblate spheroid

$$\delta=\left(\frac{ac^2}{2}\right)^{1/2}\quad\text{and}\quad\frac{E(\delta)}{E(0)}=\left(\frac{2c}{a}\right)^{2/3}\quad (4)$$

and for the prolate spheroid

$$\delta=\frac{a}{n}\quad\text{and}\quad\frac{E(\delta)}{E(0)}=\frac{1}{n}\left(\frac{b}{a}\right)^2,\quad (5)$$

where n is defined by $(a/b)^2=ne^n/2$. It is seen that the field decreases considerably at δ for the spheroid with large axis ratio. Therefore, δ gives a rough estimate of the dimension of luminous spot. The average electric field which is necessary to produce electroluminescence E_{th} is roughly estimated by equating the potential difference in the high field region between the surface and δ when E_0 is equal to E_{th} with the energy of forbidden gap I_g eV. Thus we have for the oblate spheroid

$$E_{th}=\frac{\pi}{4}\frac{I_g}{\{(2a^2c)^{1/3}-c\}}\quad (6)$$

and for the prolate spheroid

$$E_{th}=\frac{2I_g}{an}\left\{\log \left(\frac{2a}{b}\right)-1\right\}\quad (7)$$

Of course, other considerations concerning the behaviour of free electrons in high field must be added to an accurate estimation of E_{th} . Accordingly the above equations give the order of the average field intensity necessary for electroluminescence.

As examples, the ratio of the maximum field to the average, the average field strength necessary for electroluminescence and the length of luminous spot for an oblate spheroid with $a=b=1\mu$ and $c=0.1\mu$ and for a prolate spheroid with $a=1\mu$ and $b=c=0.1\mu$ are tabulated respectively in Table 1. The above

Table I. Examples of local high field around conductive spheroid.

	oblate spheroid	prolate spheroid
axes	$a=b=1\mu\ c=0.1\mu$	$a=1\mu\ b=c=0.1\mu$
$E(0)/E_0$	13	50
E_{th}	6.0×10^4 V/cm	3.7×10^4 V/cm
δ	0.17μ	0.25μ

dimensions of the conductive spheroids are chosen since the actual phosphor particles are of the order of 10μ in length. Here the energy of forbidden gap for ZnS is taken to be 3.7 eV. The calculated values are reasonable in comparison with usual experimental results.²⁾ As the shape and size of the conductive substance are quite random, the local field varies from spot to spot. Accordingly, we cannot observe the minimum applied voltage for the electroluminescence when we measure the light output from a cell as a whole. This consideration is also in agreement with experiment.^{2), 5)} The observation that the electroluminescent sensitivity of the phosphor containing much copper increases by washing in cyanide solution^{2), 13)} is explained as follows; the conductive substance, which covers too much the phosphor surface and shields the phosphor from the applied field, is partly resolved and becomes suitable in size for the electroluminescence excitation.

§ 3. Dependence of Brightness on Applied Voltage

Since the location of the high field has been

made clear in the preceding section, the dependence of electroluminescent brightness on the applied voltage will be considered in this section. Although we measure the applied voltage directly in experiments, we shall use the local field intensity in this section, as the latter is proportional to the former and is suitable for theoretical treatments. Several possible mechanisms has been considered for the electroluminescence.¹⁴⁾ Among them, the impact excitation theory is supported by many workers.²⁾ We shall also consider along this theory. The electrons introduced in the high field region are accelerated and some of them acquire sufficient energy to excite an electron from the valence band to the conduction band. The secondary electrons are also accelerated and a repetition of such electron multiplication process leads to an avalanche well known in the dielectric breakdown of solid. The holes generated in the valence band are trapped by the luminescence centers and then recombine radiatively with electrons which return to the ionized region when the direction of field is reversed. The sequence of the application of field and the emission of light is unambiguously demonstrated in the experiments by Zalm.³⁾ The luminescence center may be ionized or excited directly by a collision of accelerated electron, but the probability of such transitions would be small due to the small concentration of luminescence centers.

It is difficult to obtain the probability that an electron in the conduction band is accelerated in a uniform field to an energy sufficient to excite an electron from the valence band to the conduction band, since the interaction of electron with the lattice is not known accurately. Seitz gave the probability that an electron is accelerated to ionization energy without a collision with the lattice due to statistical fluctuation

$$P = \exp\left(-\frac{C}{E}\right), \quad (8)$$

where C is a constant.⁶⁾ The situation in electroluminescence is more complicated, as the local field is not uniform but varies considerably in a short distance; i.e., the field strength where the electron is generated differs from that where that electron makes a collision excitation. Since the average velocity of electron in the direction of field

is μE , where μ is the mobility, and $1/\tau$ is the collision frequency of electron with the lattice, the electron makes $(dx/\mu E\tau)$ collisions with the lattice while it moves dx in the field direction. Therefore, the number of secondary electrons produced while n electrons move dx is given by

$$dn = \frac{n}{\mu E\tau} \exp\left(-\frac{C}{E}\right) dx. \quad (9)$$

Exactly speaking, the interaction of electron with the lattice is a function of the energy of electron and above μ and τ are the average values of all electrons at the position where the field strength is E . Further, the probability given above is not a good approximation when the field strength increases to be comparable to C . In spite of these drawbacks, Eq. (9) will be used in the following calculations with μ and τ independent of field strength, as there is no other suitable expression for the present situation.

The variation of the local high field with position depends on the shape and size of the conductive substance. When the field at the surface of the conductive substance is E_s , the local field distribution is given generally by

$$E = \frac{E_s}{(1 + \alpha x)^m}. \quad (10)$$

Here, α and m are constants depending on the conductive substance. Using the results of the simple models in the preceding section, they are from Eq. (2)

$$\alpha = \frac{2a}{c^2} \quad \text{and} \quad m = \frac{1}{2}$$

for the field due to conductive oblate spheroid and from Eq. (3)

$$\alpha = \frac{2a}{b^2} \quad \text{and} \quad m = 1$$

for the field due to conductive prolate spheroid. From Eqs. (9) and (10), the differential equation for the electron multiplication is obtained;

$$\frac{dn}{dx} = \frac{n}{\mu E_s \tau} (1 + \alpha x)^m \exp\left\{-\frac{C(1 + \alpha x)^m}{E_s}\right\}. \quad (11)$$

The total number of electrons resulting from a primary electron, which is generated at x_0 , is given by the integration of Eq. (11) from x_0 to infinity

$$n(E_s, x_0)=\exp \left\{ \frac{1}{\alpha m \mu E_s \tau} \int_{y_0}^{\infty} y^{1/m} \cdot \exp \left(-\frac{C y}{E_s} \right) dy \right\}, \tag{12}$$

where $y=(1+\alpha x)^m$ and $y_0=(1+\alpha x_0)^m$. The primary electron is considered to be generated by the ionization of electron in traps or donors due to the action of the high field alone or the simultaneous action of the field and temperature.²⁾ Since various positions and energy levels are considered to exist for these traps or donors, the distribution of the supply of primary electron should be taken into account. Denoting the number of primary electrons generated per unit volume at x when the surface field is E_s by $\rho(E_s, x)$, and the maximum value of E_s in an alternating cycle by $E_{\max}$, the total number of secondary electrons produced in a luminous spot during a half cycle is given by integrating over field strength and volume

$$N=\int\int_0^{E_{\max}} \rho(E_s, x)\{n(E_s, x)-1\}dE_s dv. \tag{13}$$

Here ρ is not known and further detailed discussions cannot be made. However, provided that ρ is a slowly varying function of x and E_s , the values of ρ and n at $x=0$ and $E_s=E_{\max}$ contribute predominantly to the total number of secondary electrons because of the strong dependency of $n(E_s, x)$ on these variables. Therefore, for simplicity, the integrations in Eq. (13) are replaced by the substitutions of the values at $x=0$ and $E_s=E_{\max}$ and ρ is assumed constant. By performing the integration involved in Eq. (12) and putting $x_0=0$, it becomes for the field due to the conductive oblate spheroid

$$n(E_s)=\exp \left[\frac{2}{\alpha \mu \pi C} \left\{ 1+2\frac{E_s}{C}+2\left(\frac{E_s}{C}\right)^2 \right\} \right] \cdot \exp \left(-\frac{C}{E_s} \right) \tag{14}$$

and for the field due to the conductive prolate spheroid

$$n(E_s)=\exp \left[\frac{1}{\alpha \mu \pi C} \left(1+\frac{E_s}{C} \right) \exp \left(-\frac{C}{E_s} \right) \right]. \tag{15}$$

Since the magnitude of $\alpha \mu \pi C$ is an order of unity (see later section), the total number of secondary electrons is expressed in the same form irrespective of the shape of conductive spheroid if $E_{\max}$ is smaller than C

$$N=\text{const} \times \{n(E_{\max})-1\} \\ =\text{const} \times \exp \left(-\frac{C}{E_{\max}} \right). \tag{16}$$

However, if $E_{\max}$ is larger than C , the total number of secondary electrons is expressed by

$$N=\text{const} \times \exp (A E_{\max}^p), \tag{17}$$

where $p=1$ for the field due to the oblate spheroid, $p=2$ for the field due to the prolate spheroid and A is a constant depending on the size and shape of spheroid. Therefore, for the actual high field p would take a value between one and two. It should be noted that Eq. (9), from which Eq. (17) is derived, is no more a good approximation for an electric field intensity comparable to or stronger than C .

For the discussion of the dependence of brightness on the applied field, the relation between the probability of radiative recombinations and the total number of secondary electrons, i.e., the relation between the brightness and the excitation intensity, must be known. Generally the brightness of phosphor varies linearly with the excitation intensity when the excitation is weak but sublinearly when the excitation is intense. In order words, the efficiency of phosphor is constant up to a certain excitation intensity but lowers for more intense excitation. This is well known

Fig. 2. Power factor $\tan \delta$, emission intensity $B_c(\text{lm}/\text{m}^2)$ and efficiency $\eta(\text{lm}/\text{W})$ as function of applied voltage V . The frequency is constant at 120 c/s. These are obtained from measurements on electroluminescent cell giving green light¹⁶⁾.

as the saturation of brightness under the cathode-ray excitation. Similarly for the electroluminescence, when the applied voltage is not so high, the excitation is weak and the brightness is proportional to the number of secondary electrons. Accordingly, the brightness of luminous spot is from Eq. (16)

$$B_S = \alpha_S \exp\left(-\frac{\beta_S}{V}\right) \quad (18)$$

for low applied voltages, where α_S and β_S are particular constants for the spot.

Since the luminous efficiency of the electroluminescent cell decreases with increasing applied voltage as shown in Fig. 2,¹⁶ the brightness cannot be discussed from the excitation intensity alone for this voltage range. Following reasons for the saturation of brightness may be considered:

(a) When the density of impact ionization during a cycle becomes locally comparable to the density of luminescence center, the probability of nonradiative recombination rapidly increases,

(b) when the space charge in the surface region of ZnS becomes comparable to the surface charge of conductive substance, the high field intensity decreases and the probability of impact ionization diminishes and

(c) due to the high current density in the high field region, the phosphor is locally heated and the luminescence may be thermally quenched.

Experimentally it is difficult to measure the dependence of brightness of a luminous spot on the applied voltage, as the spot is very small in size and the emission intensity is weak. Several measurements have been reported but an agreement is not yet obtained among them.^{3), 6)}

The observed brightness of electroluminescent cell as a whole can be expressed over the range of several orders of magnitude by

$$B_G = \alpha_G \exp\left(-\frac{\beta_G}{\sqrt{V}}\right) \quad (19)$$

where α_G and β_G are constants and α_G is proportional to the applied frequency.³⁾ There are several other expressions similar to Eq. (19).²⁾ The emission intensity of the cell is the sum of the emission intensity of individual spot. As stated before, the conductive substance, around which local high field is produced, is quite irregular in size

and shape. Therefore, even in the voltage range where Eq. (18) is satisfied, the values of α_S and β_S are different for each luminous spot. The situation is more complicated when Eq. (18) is not satisfied as discussed above. Consequently, we can hardly discuss the quantitative dependence of brightness of electroluminescent cell on the applied voltage.

However, the explanation for the dependence of brightness on the applied frequency can be made similarly as given by previous workers^{2), 3)} irrespective of the origin of high field. As stated before, the primary electrons in the excitation process are considered to be generated by the ionization of electrons in traps or donors due to the action of electric field alone or the simultaneous action of electric field and temperature. The probability of field ionization of electrons in a certain depth from the conduction band is nearly zero under an electric field below a critical value, and rapidly increases under a field above the critical value.¹⁷⁾ Therefore, the ionization of primary electron is almost determined by the maximum applied field intensity but not by the duration while the maximum field is applied. Nearly equal excitation occurs in a cycle irrespective of the applied frequency and the average brightness is proportional to the applied frequency.

§ 4. Efficiency of Electroluminescent Cell

In this section the luminous efficiency of the electroluminescent cell will be roughly estimated. The whole phenomenon occurring in the cell under operation can be separated into several processes and the energy loss is involved in each of them. They are considered in the order of occurrence.

(1) Energy loss in ZnS

Let us consider the high field region of the phosphor particle first. When an electron moves the distance dx in the direction of field, it acquires an energy $eEdx$ and the probability of impact ionization that the electron makes during this time is given by Eq. (9). The energy necessary for the ionization is the band gap energy and this is utilized in the later process. Therefore, the energy efficiency in this acceleration and ionization processes is given by

$$\eta = \frac{I_G}{\mu\pi E^2} \exp\left(-\frac{C}{E}\right). \quad (20)$$

Assuming μ and τ are independent of the field strength, the optimum field strength is given by the condition

$$\frac{d\eta}{dE} = 0.$$

Hence, the optimum field strength is

$$E = \frac{C}{2}. \quad (21)$$

The maximum efficiency is obtained by substituting Eq. (21) into Eq. (20).

$$\eta = \frac{4I_G}{\mu\tau C^2} \exp(-2). \quad (22)$$

It is not reasonable that the efficiency of impact ionization decreases for the field strength larger than $C/2$. This is due to poor approximation of Eq. (9) for strong field strength comparable to or greater than C . Actually the efficiency would tend to unity when E approaches infinity. For the estimation of the average efficiency over the local high field region, however, the contribution from the relatively low field, where the number of electrons is much larger than that in the relatively high field, is more important. For ZnS the various constants in Eq. (22) are determined as follows: $I_G = 3.7$ eV, $\mu = 100$ cm²/volt·sec,⁹⁾ $\tau = 5.7 \times 10^{-14}$ (m^*/m) sec by the relation $\tau = \mu m^*/e$, where m^* is the effective mass of electron, and $C = 3.8 E_H$, where E_H is the breakdown field strength by von Hippel's low energy criterion.¹⁶⁾ E_H is calculated by Callen¹⁸⁾; it is at 0°C

$$E_H = \frac{2^{3/2} \pi^2 m^* e}{h^2} \hbar \omega_s \frac{\epsilon_s - \epsilon_0}{(\epsilon_s \epsilon_0^3)^{1/2}}. \quad (23)$$

For ZnS, the constants involved are; ϵ_s = static dielectric constant = 8.3, ϵ_0 = optical dielectric constant = 5.07, and $\hbar \omega_s$ = energy of reststrahl frequency = 0.035 eV. Substituting these values, it becomes $E_H = 4.46 \times 10^6$ (m^*/m) V/cm. At room temperature, correction is made and we have $C = 2.1 \times 10^6$ (m^*/m) V/cm. With these values the efficiency expressed by Eq. (22) becomes

$$\eta = 0.081 \times \left(\frac{m}{m^*} \right)^3. \quad (24)$$

We see that the efficiency varies considerably with the value of the effective mass, which is not known for ZnS and may vary with the energy of electron. Although Kröger assumed $m^* = 0.4m$ in comparison with that of CdS,⁹⁾ the substitution of his value in Eq.

(24) results an efficiency larger than unity. It is quite unreasonable to set $\eta = 1$ which means that all the electrons are accelerated to the ionization energy without dissipating energy by collisions with the lattice. However, when we consider the similarity between ZnS and CdS, it is not plausible to assume a large value of m^* . Accordingly we shall assume the efficiency of the acceleration and collision process to be approximately 2/3.

The electrons generated in the high field region drift in the average field region and reach the end of the crystal or are trapped on their way. They are drawn back to the ionized region when the applied field direction is reversed. The high field region is confined to the small spot in the phosphor particle and the number of electrons which enter into the average field region is nearly equal to that of impact ionization for high applied voltages. Therefore, it is not probably quite in an error to estimate that the energy loss in the average field region in ZnS is twice of that in the high field region at the optimum applied voltage.

(2) Energy loss in dielectric

The energy loss discussed above is due to the resistance, which is dependent on the applied field. There is another energy loss in the electroluminescent cell due to the resistance which is independent of the applied field. We know this from the value of $\tan \delta$ of the electroluminescent cell when low voltage is applied. Such an energy dissipation occurs in the dielectric and ZnS but not in the conductive substance as there is no electric field in the latter. The dissipation in the dielectric is probably larger than that in ZnS. This estimation is based on the reason that the observed value of $\tan \delta$ of the cell is nearly equal to that of dielectric although simple calculation taking into account the resistivities and volume ratio expects a greater energy loss in ZnS than that in the dielectric. The small energy loss in ZnS is considered due to the limited carried injection from the surroundings into it.

The relative magnitudes of the energy losses stated in (1) and (2) are evaluated by comparing the value of $\tan \delta$ at low applied voltages and that at the optimum voltage for the electroluminescence efficiency. In Fig. 2

the value of $\tan \delta$ at the optimum voltage is twice that at the low voltages. Hence, these two energy losses are equal in magnitude at the optimum applied voltage.

The results obtained above are shown in the diagram below. The figure in each term is the relative magnitude of energy dissipation at the optimum applied voltage.

Therefore, the energy efficiency for all these processes is $1/9$.

(3) *Efficiency of radiative recombination*

The energy efficiency of the radiative recombination of electrons and holes, which are produced by the collision ionization, is the product of the probability of the radiative recombination and the ratio of luminescence energy to the excitation energy. The latter factor represents the energy efficiency in the luminescence center. These processes are compared with those in the cathodoluminescence. Under the cathode-ray excitation, electron-hole pairs are produced on the pass of incident and secondary high speed electrons and the light is emitted when the recombination occurs at the luminescence center. In the electroluminescence, one more process is added, i.e., the secondary electrons are swept away in the field direction and then drawn back to the ionized region. Hence, the probability of radiative recombination in the electroluminescence is not larger but possibly smaller than that in the cathodoluminescence. The energy efficiency in the luminescence center is the same for both excitation methods. According to the measurement by Brill and Klasens, the energy efficiency of green luminescence of ZnS:Cu, Al phosphor is 25% under 20 kV cathode-ray excitation.¹⁹⁾ In the cathode-ray excitation, the total incident energy is not utilized for the excitation and the average energy dissipated to produce an electron-hole pair is arbitrarily estimated to be $1.5 I_0$, as an electron with energy more than I_0 can produce another pair. We are here concerned with the efficiency of radiative recombination of already produced electrons. Accordingly, the energy efficiency in these processes is $0.25 \times 1.5 = 0.38$.

(4) *Absorption of luminescence*

It is practically impossible to take out the whole luminescence emitted in the phosphor from the front surface of the electroluminescent cell. For example, the luminescence emitted backward suffers a considerable loss, even in the presence of the reflection plate, and the transparent electrode absorbs the luminescence to some extent. Therefore, the luminescence energy taken out from the front surface is probably $2/3$ of the total. This estimation is made by an analogy with the light output from the glass side of cathode-ray tube screen.¹⁹⁾

The luminous efficiency of the electroluminescent cell is estimated from the considerations given above. The spectrum of green luminescence of ZnS:Cu phosphor has a lumen equivalent of about 450 lm/W. Taking the product of efficiencies for each process, we have for the luminous efficiency of the cell emitting green light

$$450 \times \frac{1}{9} \times 0.38 \times \frac{2}{3} = 13 \text{ lm/W}.$$

Although the above estimation is quite rough and gives an order of the maximum luminous efficiency, the result is approximately equal to the maximum efficiency observed up to the present¹⁰⁾. The efficiency lower than this is easily understood. For the applied voltage lower than the optimum, the efficiency of the acceleration and ionization process diminishes and further the ratio of energy loss in the high field region to that in the dielectric decreases. For the applied voltage higher than the optimum, the decrease in efficiency can be explained by the several reasons stated in the preceding section. It would be unnecessary to mention the low efficiency of phosphor which is not suitable for electroluminescence excitation.

The author expresses his sincere thanks to

Dr. Y. Uehara for his valuable discussions and kind reading of the manuscript and to Dr. H. Miyazawa for his helpful discussions.

Phenomenological Free Streamline Theory, Part I. Flow past a Normal Plate

By Yōichi MIMURA

Faculty of Science, Hiroshima University, Hiroshima

(Received June 23, 1958)

The flow past a normal plate is discussed phenomenologically by the free streamline theory. The pressure distribution on the normal plate is determined by the pressure distribution on a free streamline which is obtained as a function of the distance from the separation point. In case when the latter is obtained only in the "free streamline range" (e.g., the range from the separation point to a distance equal to about one and a half of the breadth of the plate), the pressure distribution and other quantities on the normal plate are estimated with their probable deviations. The shape of the free streamline is also examined.

§ 1. Introduction

It is well known* that the free streamline theory of the Kirchhoff type gives satisfactory results for the free jet problem and related ones. By the use of the theory, Kirchhoff himself calculated the resistance of a plane lamina with wake, thus dissolving the d'Alembert paradox, but no satisfactory result in good agreement with observations has yet been obtained. Recently Roshko¹⁾ and Woods²⁾ improved the theory by assuming the pressure distributions on the free streamlines to be variable, and good results have been obtained by Roshko in the case of flow past a normal plate and also by Woods in the case of flow past a circular cylinder. However, they postulated data on the free streamlines intuitively.

* The historical review of the free streamline theory has been given by several writers. See, for instance, Birkhoff's book: "*Hydrodynamics. A Study in Logic, Fact, and Similitude*" (Princeton Univ. Press, 1950).

We shall now consider the problem to dis-

cuss phenomenologically the observed distribution of pressure coefficient C_{pw} on the front surface of a body with wake by the free streamline theory*. Here the front (wetted) surface is referred to as a part of the surface of the body ranging from the stagnation point to two separation points. We assume that the observed pressure coefficient C_{pw} is equal to that as calculated by the theory of perfect fluid flow with free streamlines. The pressure coefficient on the free streamline thus assumed, expressed as a function of streamwise distance x from the separation point, is denoted by $C_{pR}(x)$.

It is known experimentally that the shear layer is thin and approximately steady in a certain range of distance downstream the separation point, which is of the order of the length of the body. We call provisionally such a range the "free streamline range", and we assume for simplicity that the pressure distribution in this range can be obtained definitely by the observation in the shear layer. We denote it by $C_{pE}(x)$. It is expected that this $C_{pE}(x)$ is closely related to $C_{pR}(x)$ (cf. § 7 (4)).

In the further downstream range, however, the shear layer becomes broader and broader and at the same time non-uniformity of the pressure distribution across the layer increases and finally the layer rolls up into Kármán vortex street or becomes directly the region of turbulent mixing. In such a range, which we call here provisionally the "mixing range", the shape of the free streamline as well as the pressure coefficient $C_p(x)$ cannot be determined definitely, so that it is insignificant to treat them either phenomenologically or theoretically (cf., e.g. the introduction of ref. 1)). The boundary of the above two ranges is of course altered according to the treatment of the problem.

Thus, in the phenomenological free streamline theory it is desirable to discuss the flow by the use of $C_{pE}(x)$ alone and also to study the determination of $C_{pE}(x)$ from the observation in the wake. The standpoint that the drag of a body is determined by the use of data near the body is in contrast to the

theories in which, like the theory of Kármán vortex street, the drag is determined by the use of data at a great distance from the body.

Thus, the problems to be discussed in the phenomenological free streamline theory may be summarised as follows:

Problem I. When the pressure distributions on the free streamlines, $C_{pE}(x)$, are known only in the finite "free streamline ranges", to what extent the pressure distribution, C_{pw} , and other quantities on the wetted surface of the body as well as the shape of the free streamlines can be determined?

Problem II. When C_{pw} is known within experimental error, to what extent $C_{pR}(x)$ as well as the shape of the free streamlines can be determined?

Problem III. How the mechanism of the wake near the body should be approximated experimentally or theoretically by the free streamlines and what should be the general law which may be determined from this approximation?

In the present paper we shall discuss Problem I in the case of a normal plate. A study of uncertainty of $C_{pE}(x)$ in the real shear layer and its effect upon C_{pw} and other quantities is a further advanced problem relating to Problem I. The discussion on other cases in Problem I than the case of a normal plate as well as on Problems II and III will be postponed to later papers.

§ 2. Method of Woods

We shall now discuss the above-mentioned Problem I by the method of Woods³⁾, an outline of which may be given in this section.

With the origin of coordinate-axes (x, y) at a certain point on the body, we take the x - and y -axes parallel and perpendicular to the undisturbed flow respectively, and we denote, as usual, the complex coordinate by $z = x + iy$. Then, if we denote the complex potential by w and the magnitude and the direction of the fluid velocity at any point in the flow field by q and θ respectively, we have

$$\frac{dz}{dw} = \frac{1}{q} e^{i\theta}. \quad (2.1)$$

Following Woods, we map the w -plane onto a $\zeta (= \eta + i\gamma)$ -plane by the relation:

$$w = 4\alpha(i \sinh \frac{1}{2} \zeta + \sin \frac{1}{2} \lambda)^2, \quad (2.2)$$

where α and λ are constants to be chosen

* Throughout the present paper the physical quantities with the suffix w refer to the wetted surface, while those without it refer to the free streamlines only.

adequately so that the wetted surface of the body is mapped onto the line-segment $\eta=0$, $-\pi\leq\tau\leq\pi$ and the free streamlines are mapped onto two parallel semi-infinite straight lines $\eta\leq 0$, $\tau=\pm\pi$. According to Woods, the function $f=\ln(e^{i\theta}/q)$ in the ζ -plane is given by

$$f(\zeta)=i\theta_w(-\pi)-\frac{1}{\pi}\int_{\eta^*=-\pi}^{\pi}\ln\frac{\sin\frac{1}{2}(\tau^*+i\zeta)}{\cos\frac{1}{2}(\tau^*-i\zeta)}d\theta_w(\tau^*)-\frac{\cosh\frac{1}{2}\zeta}{2\pi}\int_0^{-\infty}\left\{\frac{\Omega_+(\eta^*)}{\cosh\frac{1}{2}\eta^*+i\sinh\frac{1}{2}\zeta}+\frac{\Omega_-(\eta^*)}{\cosh\frac{1}{2}\eta^*-i\sinh\frac{1}{2}\zeta}\right\}d\eta^*,\tag{2.3}$$

where

$$f=-\Omega+i\theta,\tag{2.4}$$
$$\Omega=\ln q,\tag{2.5}$$

$\theta_w(r)$ being the value of θ on the wetted surface, and $\Omega_+(\eta)$, $\Omega_-(\eta)$ being respectively the values of Ω on the upper and the lower free streamlines, while τ^* and η^* being integration variables.

When the shape of the wetted surface of the body and $\Omega_+(\eta)$, $\Omega_-(\eta)$ on the free streamlines are prescribed, implying that the angle of attack, the positions of the two separation points and the separation velocities q_s are known, the flow can be determined by (2.3). In the case of symmetric flow where we always concern only with the upper free streamline and denote Ω_+ simply by Ω , Woods proposed a convenient form for Ω as:

$$\Omega=\frac{\ln q_s}{1+b^2\sinh^2\frac{1}{2}\eta},\tag{2.6}$$

(b : a constant),

which was deduced by assuming that far downstream on the free streamline, i.e. when $x\gg 1$,

$$q-1\approx\beta x^{-1},\quad (x\gg 1)\tag{2.7}$$

β being a constant. Such an assumption is quite legitimate, e.g. in the cases of the free streamlines which are deduced by Roshko using the method of the elliptic hodograph¹⁾ and of the notched hodograph¹⁾.

The condition that the upper and the lower free streamlines do not cross each other is given by:

$$\int_{-\pi}^{\pi}\theta_w(\tau^*)\sin\frac{1}{2}\tau^*d\tau^*+\int_0^{-\infty}\{\Omega_+(\eta^*)+\Omega_-(\eta^*)\}\cosh\frac{1}{2}\eta^*d\eta^*\geq 0,\tag{2.8}$$

which is referred to as the ‘‘condition of physical reality’’. The equality in (2.8) holds when the width of the two free streamlines at infinity is finite. We shall call Ω given by (2.6) the ‘‘Woods type’’ when it satisfies such a condition of finite width.

§ 3. Application to the Case of a Normal Plate

(1) We now consider the flow past a normal plate placed in a uniform flow. We adopt such units of length and time that both the breadth of the plate and the magnitude of the undisturbed velocity become unity.

In the present case $\theta_w(r)$ is given by

$$\left.\begin{aligned}\theta_w(r) &= -\pi/2, & (-\pi\leq r\leq 0), \\ \theta_w(r) &= \pi/2, & (0\leq r\leq \pi),\end{aligned}\right\}\tag{3.1}$$

and λ in (2.2) is equal to zero.

In order to express physical quantities conveniently, we use, on the free streamlines,

$$X=-\sinh(\eta/2),\quad (0\leq X\leq\infty),\tag{3.2}$$

while, on the wetted surface of the body,

$$W=\cos(r/2),\quad (0\leq W\leq 1).\tag{3.3}$$

Then, using (2.1)~(2.5), the physical quantities are written as follows. Namely, on the wetted surface ($\zeta=i\tau$), where $W=0$ at the separation points and $W=1$ at the stagnation point, we have

$$q_w(W)=q_s\sqrt{\frac{1-W}{1+W}}e^{-W\phi(W)},\tag{3.4}$$

with

$$G(W)=\frac{2}{\pi}\int_0^{\infty}\{\Omega(0)-\Omega(X^*)\}\frac{dX^*}{W^2+X^{*2}},\tag{3.5}$$

$$y_w(W)=N\int_0^Wq_w^{-1}(W^*)W^*dW^*,\tag{3.6}$$

where

$$N^{-1}=2\int_0^1q_w^{-1}(W^*)W^*dW^*,\tag{3.7}$$

the coordinate y_w having been measured from the lower separation point.

On the other hand, we have, on the upper free streamline ($\zeta=\eta+i\pi$) where $X=0$ at the separation point and $X=\infty$ at the point at infinity,

$$q(X)=\exp\Omega(X),\tag{3.8}$$

$$\theta(X)=\cot^{-1}X-H(X),\tag{3.9}$$

with

$$H(X)=\frac{2}{\pi}X\operatorname{Re}\left\{\int_0^{\infty}\Omega(X^*)\frac{dX^*}{X^2-X^{*2}}\right\},\tag{3.10}$$

where Re means "the real part of", and

$$x(X) = N \int_0^X q^{-1}(X^*) \cos \theta(X^*) X^* dX^*, \quad (3.11)$$

$$y(X) = N \int_0^X q^{-1}(X^*) \sin \theta(X^*) X^* dX^*, \quad (3.12)$$

x and y having been measured from the upper separation point. By (2.8) the condition of physical reality now turns out to be

$$\int_0^\infty \mathcal{Q}(X^*) dX^* < \pi/2, \quad (3.13)$$

and the condition of finite width becomes

$$\int_0^\infty \mathcal{Q}(X^*) dX^* = \pi/2. \quad (3.14)$$

(2) By the use of the above formulae we shall discuss briefly the manner in which $\mathcal{Q}(X^*)$ in the range $X^* \gg 1$ affects quantities on the wetted surface of the plate as well as on the free streamlines in the vicinity of the body where $X \lesssim 1$. It is readily found that since the function $G(W)$ in (3.5) has the damping factor $(W^2 + X^{*2})^{-1}$, the range of X^* in which $\mathcal{Q}(X^*)$ affects remarkably the quantities on the wetted surface is short. Also we see that the range of X^* in which $\mathcal{Q}(X^*)$ affects remarkably the quantities on the free streamline in the vicinity of the separation point is short too, because the function $H(X)$ in (3.10) has the damping factor $(X^2 - X^{*2})^{-1}$. But the latter damping factor becomes infinite at $X^* = X$, implying that the shape of the free streamline is much more affected by $\mathcal{Q}(X^*)$ than the quantities on the wetted surface. The detailed discussions on these points will be given in §§ 6~8.

Similarly to the above case, the effect of $\mathcal{Q}_\pm(X)$ can also be discussed by (2.3) for the case of asymmetric flow past an arbitrary body by resolving $\mathcal{Q}_\pm(X)$ into symmetric and antisymmetric parts. The interpretation of these damping effects which behave approximately as X^{*-2} has been given phenomenologically by Prof. T. Maekawa (cf. § 7 in ref. 3).

(3) When $\mathcal{Q}(X)$ is given by (2.6), i.e. when

$$\mathcal{Q}(X) = \frac{\ln q_s}{1 + b^2 X^2}, \quad (0 \leq X \leq \infty), \quad (3.15)$$

the integrals involving $\mathcal{Q}(X^*)$ in (3.5), (3.10), (3.13) and (3.14) can be easily evaluated. Thus we have

$$G(W) = \ln q_s \cdot b(1 + bW)^{-1}, \quad (3.16)$$

$$H(X) = \ln q_s \cdot bX(1 + b^2 X^2)^{-1}, \quad (3.17)$$

and the condition of physical reality becomes

$$b \geq \ln q_s. \quad (3.18)$$

Since $\mathcal{Q}(X^*)$ for large X^* has only small effects upon $G(W)$ and $H(X)$, the functions $G(W)$ and $H(X)$ for $X \gg 1$ may be approximated by (3.16) and (3.17) respectively in which the value of b is so determined as to approximate $\mathcal{Q}(X)$ by (3.15) near $X=0$.

If we denote $\mathcal{Q}(X)$ of the Woods type by $\mathcal{Q}_W(X)$, we have, by (3.15) and (3.18),

$$\mathcal{Q}_W(X) = \frac{\ln q_s}{1 + (\ln q_s)^2 X^2}, \quad (0 \leq X \leq \infty). \quad (3.19)$$

If, in this case, we determine $C_p(X)$ by (3.8) and $x(X)$ by (3.11), (3.9) and (3.17), the behaviour of $C_p(x)$ near the separation point is represented by $\{C_p(x) - C_p(0)\}^{3/2} \propto x$. This behaviour should be compared with that of $C_p(x)$ as treated by the notched hodograph (cf. § 6 in ref. 3)). The calculated results by the use of the Woods type, together with the results for other cases, will be given in § 5. It will be seen from Table I there that the value of C_{Nw} , i.e., the sum of C_{pw} over the wetted surface, as obtained by the use of the Woods type is too large.

§ 4. Procedure of Determining the Flow by the Use of Observed Pressure Distribution on the Free Streamline

Taking the case of normal plate we shall explain the procedure of determining the flow when the value of C_p is obtained experimentally as a function of x . The procedure can however be extended to the case of a body of arbitrary shape. In accordance with the discussion in § 1, we assume that $C_p = C_{pE}(x)$ is obtained definitely in the free streamline range.

To begin with, we calculate $\mathcal{Q} \equiv \mathcal{Q}_E(x)$ corresponding to $C_p = C_{pE}(x)$ by the relation $C_p = 1 - q^2 = 1 - \exp(2\mathcal{Q})$. To a first approximation, we first take an approximate value for $\mathcal{Q}(X)$ in $0 \leq X \leq \infty$ which will be denoted as $\mathcal{Q}^I(X)$, and then, by aid of (3.7) we determine N^I on the wetted surface.* In the next place, we determine, by (3.11), the value of x on the free streamline, which will be denoted as $x^I(X)$, and if we insert this value of x into $\mathcal{Q}_E(x)$, we obtain the second approxi-

* Indices $I, II, \dots$ will be used to denote the order of successive approximations.

ximation of $\mathcal{Q}(X)$, i.e. $\mathcal{Q}^{II}(X)=\mathcal{Q}_E(x^I(X))$. In like manner, further approximations $\mathcal{Q}^{III}(X)$, $\mathcal{Q}^{IV}(X)$, ... can be obtained. As will be proved in § 8 (2a), the successive approximations converge rapidly.

When $C_{pE}(x)$ is obtained experimentally in the finite free streamline range $x\leq x_M$, we must, in addition, supply $C_p(x)$ in the mixing range $x\geq x_M$. Alternatively, we may appropriately choose $\mathcal{Q}(X)$ in $X\geq D$ in each order of successive approximations, where D is so chosen that $x(D)$ corresponds to x_M . The value of D can easily be determined approximately since $x(X)$ is insensitive to $\mathcal{Q}(X)$, especially $x(X)$ in $X\leq D$ is almost insensitive to the choice of $\mathcal{Q}(X)$ in $X\geq D$ as will be shown in § 8 (1c) and (2b).

The practical method of determining $\mathcal{Q}^N(X)$ ($N\geq 2$) is as follows. First, $\mathcal{Q}^N(X)$ in $X\leq D$ can be determined when $\mathcal{Q}^{N-1}(X)$ is determined for $0\leq X\leq\infty$. Next, as $\mathcal{Q}^N(X)$ in $X\geq D$ we choose the form

$$\mathcal{Q}_a(X)=\mathcal{Q}(D)D^2X^{-2}, \quad (X\geq D), \quad (4.1)$$

and put D^N and $\mathcal{Q}^N(D^N)$ in place of D and $\mathcal{Q}(D)$ respectively, D^N being the value of D in the n th approximation. We denote $\mathcal{Q}_a(X)$ thus determined as $\mathcal{Q}_a^N(X)$. As will be explained in detail in § 7, by virtue of the simple form of $\mathcal{Q}_a^N(X)$, we can easily estimate the probable errors involved in the calculation of C_{Nw} and other quantities arising from this choice. Hence we can estimate the value of D^N in order to determine C_{Nw} within experimental error (see § 7 (3)).

§ 5. The Solution for the Case of a Normal Plate

As an example we shall here deal with the flow past a normal plate by applying the method described in the preceding section. As for $C_{pE}(x)$ we first adopt the one which is determined by the elliptic hodograph used by Roshko¹⁾, and also we use the value of 1.545 for q_s which was observed by Fage and Johansen.⁴⁾ In the present case $D=\infty$. For the first approximation of $\mathcal{Q}(X)$ we have used the Woods type (3.19). As mentioned in § 3 the convergency of successive approximations is rapid, and the second and third approximations of $\mathcal{Q}(X)$, i.e. $\mathcal{Q}_{\text{ellip}}^{II}(X)$ and $\mathcal{Q}_{\text{ellip}}^{III}(X)$, nearly coincide with each other (Fig. 1). We may therefore consider $\mathcal{Q}_{\text{ellip}}^{III}(X)$ as the final form of $\mathcal{Q}(X)$, which may be

approximated by the form (3.15), namely:

$$\mathcal{Q}_L(X)=\frac{\ln q_s}{1+b^2X^2}, \quad (\text{with } b=1.2), \quad (5.1)$$

(cf. Fig. 1).

We have determined the flow by making use of (5.1) in place of the elliptic hodograph obtaining the results as shown below.

Next we have adopted for $C_{pE}(x)$ the experimental curve obtained by Roshko¹⁾, modifying it in the vicinity of the separation point in such a manner that q_s takes the value of 1.545 (see Fig. 3), and we denote the resulting modified curve by $C_{p\text{exp}}(x)$ and the quantities in this case by attaching the suffix "exp". The adequacy of such a modified curve will be discussed in § 7 (4).

In order to determine the flow we have used, as in the above case, the formula (3.19) for the first approximation, and for higher approximations we have followed the treatment of the case where $\mathcal{Q}_E(x)$ is obtained only in a finite range. Here we have determined D^N without the use of the method described in the last paragraph. For the second approximation D^{II} has been determined by $x^I(D^{II})\approx 1$ under the consideration that the free streamline range may be of about this length. For the third approximation we have chosen $D^{III}=3.12$ so that (3.14) is satisfied by $\mathcal{Q}_{\text{exp}}^{III}(X)$. Concerning these choices of D^{II} and D^{III} we will discuss in § 7 (3) and (4) respectively.

The calculated results are shown in Tables I, II and Figs. 1~5,* together with the results as obtained by using Woods type (3.19) and the elliptic hodograph (5.1). For comparison the calculated results for the Kirchhoff flow, in which $\mathcal{Q}_K(X)=0$ in $0\leq X\leq\infty$, and for the notched hodograph devised by Roshko, as well as the experimental results obtained by Fage and Johansen are also shown in these tables and figures.

Table I shows C_{Nw} for various cases, while Table II gives the values of D , $\mathcal{Q}(D)$, $x(D)$, N and d' where $d'=1+2y(\infty)$ is the distance between the two free streamlines at infinity. Figs. 1~5 show $\mathcal{Q}(X)$, $x(X)$, $y(X)$, $C_p(x)$, $C_{pw}(y_w)$ and the shape of the upper free streamline.

The calculations have been performed correct to four significant figures, using the

once determined data of $\Omega_{\text{exp}}(x)$, in order to discuss the convergency of successive approximations and the errors of approximate formulae in the succeeding paragraphs.

The convergency of successive approximations in the case of $\Omega_{\text{exp}}(x)$ is somewhat

Fig. 2. $x(X)$ and $y(X)$ on the upper free streamlines for various cases (the breadth of a normal plate is taken as unity). d_K is the lateral spacing of Kármán vortex street.

worse than that in the case of $\Omega_{\text{ellip}}(X)$ owing to arbitrary choice of D and $\Omega(X)$ in $X \geq D$.

In case when we use the result of experiment, however, the final form of $\Omega(X)$, i.e.

Fig. 5. The shapes of the upper free streamlines for various cases.

$\mathcal{Q}_{\text{exp}}(X)$, can be determined only when $\mathcal{Q}_{\text{exp}}(X)$ is determined in $0 \leq x \leq \infty$, but, as will be shown in §8 (2b), it is nearly equal to $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$ in $X \leq D$. Other calculated results will be discussed in §§ 6~8.

§ 6. Approximate Formulae for Quantities on the Front Surface of the Normal Plate, as determined by $\mathcal{Q}(X)$

From Fig. 1 it is seen that there are three

typical types of $\mathcal{Q}(X)$, namely: $\mathcal{Q}_L(X)$, $\mathcal{Q}_W(X)$ and $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$. However, $\mathcal{Q}(X)$ may take also various forms experimentally. Thus, the two-dimensional flow past a body whose wetted surface forms a normal plate can be treated by the free streamline theory as the flow past the normal plate irrespectively of the shape of the back surface as well as the Reynolds number. In this paragraph we give approximate formulae for quantities on the front surface of the normal plate as determined by various $\mathcal{Q}(X)$.

(1) *General formulae.* Following the discussion in § 3 (3), we may approximate $G(W)$ by (3.16), so that, choosing b properly, we have

$$WG(W) \approx WG(1) + \frac{bW(1-W)}{1+bW}G(1). \tag{6.1}$$

Neglecting the second term and noting that the first term is small, we put

$$\exp \{ WG(W) \} \cdot (1 + \varepsilon(W)) = 1 + rW, \tag{6.2}$$

with

$$r = \exp G(1) - 1. \tag{6.3}$$

The value of r is shown in Table IV. Since, as will be shown in Appendix 1, the value of $\varepsilon(W)$ is fairly small, we shall put $\varepsilon(W) = 0$ in the following lines.

Using (6.2) and (3.4) $q_w(W)$ is approximated by

$$q_w(W) = q_s \sqrt{\frac{1-W}{1+W}} \frac{1}{1+rW}. \tag{6.4}$$

Then approximate formulae for various quantities on the front surface of the normal plate can be easily obtained. Namely, putting

$$\left. \begin{aligned} A_n &= \int_0^1 \sqrt{\frac{1-W}{1+W}} W^n dW, \\ B_n &= \int_0^1 \sqrt{\frac{1+W}{1-W}} W^n dW, \end{aligned} \right\} \tag{6.5}$$

$(n=1, 2, \dots)$

thus, e.g. $A_1 = 1 - \pi/4$, $A_2 = \pi/4 - 2/3$, $A_3 = 2/3 - 3\pi/16$, $A_4 = 3\pi/16 - 8/15$, $B_1 = 1 + \pi/4$, $B_2 = \pi/4 + 2/3$ and $B_3 = 2/3 + 3\pi/16$, we obtain by (3.7)

$$N = q_s/2(B_1 + B_2r). \tag{6.6}$$

Using its definition as well as (3.6), C_{Nw} can be expressed as

$$\begin{aligned} C_{Nw} &= \int_{-1}^1 C_{pw}(y_w) d(y_w) \\ &= 1 - 2N \int_0^1 q_w(W^*) W^* dW^*. \end{aligned} \tag{6.7}$$

Thus, expanding $(1+rW)^{-1}$ and neglecting terms of $O(r^3)$ we obtain

$$C_{Nw}=1-q_s^2(A_1-A_2r+A_3r^2)/(B_1+B_2r). \quad (6.8)$$

The accuracy of the above two approximate formulae (6.6) and (6.8) will be examined in Appendix 1.

Next we shall estimate the deviations of the quantities on the front surface of the normal plate due to Δr , which denotes the deviation of r caused by $\Delta \mathcal{Q}(X)$, by neglecting terms of the order $O(r^3)$ and $O(\Delta r)^2$. The maximum deviation including sign (i.e., one of the maximum and minimum of the deviation which has a larger absolute value) of $C_{pw}(=1-q_w^2)$ is given by

$$(\Delta C_{pw})_{\max}=2q_s^2\frac{1-W}{1+W}\frac{W}{(1+rW)^3}\Delta r, \quad (6.9)$$

where

$$W=W_p=\sqrt{2}-1+0.5(10-7\sqrt{2})r+O(r^2).$$

The calculated value of $y_w(W)$ at $W=W_p$ in the cases in Fig. 4 is about 0.03.

Using (6.6) and (6.8) the deviations of N and C_{Nw} are found to be given respectively by

$$\Delta N=-2N(N/q_s)B_2\Delta r=-2.904N(N/q_s)\Delta r, \quad (6.10)$$

and

$$\begin{aligned} \Delta C_{Nw} &= 4N^2(A_1B_2+A_2B_1-2A_3B_1r-2A_3B_2r^2)\Delta r \\ &= (2\pi/3)N^2(1-0.5293r-0.431r^2)\Delta r. \end{aligned} \quad (6.11)$$

(2) *Application.* We shall next apply the above formulae to various $\mathcal{Q}(X)$ in Fig. 1. When $C_p(x)$ is pushed down, $\mathcal{Q}(x)$ is pushed up and hence $\mathcal{Q}(X)$ is also pushed up (noting that $\Delta x(X)$ caused by $\Delta \mathcal{Q}(X)$ is always small (cf. § 8 (1c)), so that r is decreased by (3.5) and (6.3) (cf. Table IV). Hence $(C_{pw})_{\max}$ and C_{Nw} decrease by (6.9) and (6.11) respectively, but N increases by (6.10). This is found to be the case in Figs. 3 and 4 and Table I (cf. the membrane analogy: § 7 [2] in ref. 4). $(C_{pw}(y_w))$ and C_{Nw} coincide well with each other in the cases of the notched hodograph and of the experiment and it is explained by the fact that r may be almost equal for both cases.)

Table III shows the accuracy of the approximate equations (6.9)~(6.11). The first column of the numerical data gives the approximate values of the deviations, Δ_{appr} , of the quantities in the case of $\mathcal{Q}_{\text{exp}}^I(X)$ from those in the case of $\mathcal{Q}_{\text{exp}}^{III}(X)$ and the second column gives the exact values of these deviations, Δ_e ,

Table III. The approximate and the exact deviations for various quantities of the first and the second approximations in the case of $\Omega_{\text{exp}}(x)$.

	$\text{exp}^I - \text{exp}^{III}$			$\text{exp}^{II} - \text{exp}^{III}$		
	$\frac{\Delta_{\text{appr}}}{(\times 10^{-2})}$	$\frac{\Delta_e}{(\times 10^{-2})}$	$\frac{\Delta_{\text{appr}}}{\Delta_e} - 1$	$\frac{\Delta_{\text{appr}}}{(\times 10^{-4})}$	$\frac{\Delta_e}{(\times 10^{-4})}$	$\frac{\Delta_{\text{appr}}}{\Delta_e} - 1$
$(\Delta C_{pw})_{\max}$	3.29	4.86	-0.32	12	29	(-0.6)*
ΔN	-1.37	-1.45	-0.055	- 5	- 8	(-0.4)
ΔC_{Nw}	1.38	1.61	-0.14	5	7	(-0.3)

* The values of the last column are shown in brackets as they are rough.

while the third column gives the values of $(\Delta_{\text{appr}}/\Delta_e)-1$. The remaining columns give the corresponding values in the case of $\mathcal{Q}_{\text{exp}}^{II}(X)$ as compared with $\mathcal{Q}_{\text{exp}}^{III}(X)$. It will readily be seen from this table that the convergence of approximate values of various quantities is rapid.

(3) Owing to the rapid convergence of the values of C_{Nw}^N we have

$$(\Delta_e C_{Nw})^N, \infty \approx (\Delta_e C_{Nw})^{N, N+1}, \quad (6.12)$$

where, for example, $(\Delta_e C_{Nw})^N, \infty$ means the exact deviation of the n th approximate value

of C_{Nw} from its final value. Hence from Table III we have $(\Delta_e C_{Nw})^I, \infty \approx 2 \times 10^{-2}$, $(\Delta_e C_{Nw})^{II}, \infty \approx 1 \times 10^{-3}$. Furthermore, in the calculation of C_{Nw}^{IV} we choose D^{IV} equal to D^{*III} and we have $(\Delta_e C_{Nw})^{III}, \infty \approx 1 \times 10^{-4}$. For rough estimation we may use (6.11) and put $(\Delta_e C_{Nw})^N, \infty \approx (\Delta_{\text{appr}} C_{Nw})^N, N+1$.

§ 7. Effect of the Deviation of $\mathcal{Q}(X)$ in the Mixing Range

Next, we shall estimate deviations of the quantities on the front surface of the normal

plate caused by uncertainty of $\mathcal{Q}(X)$ in the mixing range $X \geq D$. Such deviations will be denoted by δ , distinguishing them from the deviations, denoted by Δ , caused by the general deviation of $\mathcal{Q}(X)$. In this paragraph, $\mathcal{Q}(X)$ in $X \leq D$, i.e. $\mathcal{Q}_E(X)$, is supposed to be given definitely.

(1) *General formulae.* First, we derive convenient formulae to estimate the deviations δC_{Nw} of C_{Nw} and δN of N . Let $G_M(W)$ denote the contribution of $\mathcal{Q}(X)$ in $X \geq D$ to $G(W)$. Then we have, by (3.5),

$$G_M(W) = -\frac{2}{\pi} \int_D^\infty \frac{\Omega(X^*)}{W^2 + X^{*2}} dX^* \quad (7.1)$$

Simplifying the approximate expression (6.2), we put

$$\exp\{WG_M(W)\} \cdot (1 + \epsilon_M(W)) = 1 + WG_M(1), \quad (7.2)$$

and use the approximation: $\epsilon_M(W) = 0$. The ratio of error of this approximation, $\epsilon_M(W)$, and the errors in the calculations using this approximation will be examined in Appendix 2.

The deviation of $G(W)$ which arises from $\delta \mathcal{Q}(X)$ is denoted by $\delta G_M(W)$. Following the approximate method in (7.2) we put

$$\exp\{W\delta G_M(W)\} \cdot (1 + \delta \epsilon_M(W)) = 1 + W\delta G_M(1), \quad (7.3)$$

and neglect $\delta \epsilon_M(W)$. Further we put

$$\left. \begin{aligned} A_n' &= \int_0^1 \sqrt{\frac{1-W}{1+W}} e^{-W\mathcal{G}(W)} W^n dW, \\ B_n' &= \int_0^1 \sqrt{\frac{1+W}{1-W}} e^{W\mathcal{G}(W)} W^n dW. \end{aligned} \right\} \quad (n=1, 2, \dots) \quad (7.4)$$

Then, by (6.7) and (3.4), neglecting $O(\delta G_M(1))^2$, we have

$$\delta C_{Nw} = q_s^2 (A_1' B_2' + A_2' B_1') B_1'^{-2} \delta G_M(1), \quad (7.5)$$

which, by using (6.2) and (6.5) and neglecting terms of $O(r^3)$, is further simplified to

$$\begin{aligned} \delta C_{Nw} &= 4N^2 \{A_1 B_2 + A_2 B_1 \\ &\quad - (A_2 B_3 - A_4 B_1) r^2\} \delta G_M(1) \\ &= (2\pi/3) N^2 (1 - 0.095 r^2) \delta G_M(1). \end{aligned} \quad (7.6)$$

Here, by (3.7) and (3.4), $N = q_s/2B_1'$.

Similarly, by (3.7), δN becomes

$$\begin{aligned} \delta N &= -2N(N/q_s)(B_2 + B_3 r) \delta G_M(1) \\ &= -2N(N/q_s)(1.4521 + 1.2557r) \delta G_M(1). \end{aligned} \quad (7.7)$$

(2) *Formulae to estimate $|\delta C_{Nw}|_{\max}$.* To find δC_{Nw} by (7.6) it is necessary to estimate

$\delta G_M(1)$. In the mixing range there may exist the most adequate $\mathcal{Q}(X)$ which is denoted by $\mathcal{Q}_t(X)$. ($\mathcal{Q}_t(X)$ may have different form for each order of approximations corresponding to, e.g. different $\mathcal{Q}^N(D^N)$.) We here postulate a probable and most simple limitation to $\mathcal{Q}_t(X)$ as: $0 \leq \mathcal{Q}_t(X) \leq \mathcal{Q}_E(D)$ in $X \geq D$.

We use three forms of $\mathcal{Q}(X)$ in $X \geq D$ and discriminate those by suffices a, b and c. The form (a) is represented by (4.1) and the other two forms are defined respectively by

$$\text{form (b): } \mathcal{Q}_b(X) = \mathcal{Q}(D), \quad (X \geq D), \quad (7.8)$$

$$\text{form (c): } \mathcal{Q}_c(X) = 0, \quad (X \geq D). \quad (7.9)$$

These forms are shown in Fig. 6.

Fig. 6. Sketch of various forms of $\mathcal{Q}(X)$ in $X \geq D$.

By the use of (7.1) we have calculated $WG_M(W)$ in each of the forms (a), (b) and (c), obtaining

$$WG_{Ma}(W) = -\frac{2}{\pi} \mathcal{Q}(D) \left\{ \frac{D}{W} - \left(\frac{D}{W} \right)^2 \tan^{-1} \frac{W}{D} \right\}, \quad (7.10)$$

$$WG_{Mb}(W) = -\frac{2}{\pi} \mathcal{Q}(D) \tan^{-1} \frac{W}{D}, \quad (7.11)$$

$$WG_{Mc}(W) = 0. \quad (7.12)$$

We shall estimate the upper limit of $|(\delta G_M(1))_{at}|$, where, for example, we denote $G_{Ma}(1) - G_{Mt}(1)$ by $(\delta G_M(1))_{at}$. When $|(\delta G_M(1))_{at}|$ becomes maximum, $\mathcal{Q}_a(X) - \mathcal{Q}_t(X)$ should have the definite sign by (7.1), so that using (7.10) and (7.11), we have

$$\begin{aligned} |(\delta G_M(1))_{at}| &\leq \max \{(\delta G_M(1))_{ab}, -(\delta G_M(1))_{ac}\} \\ &= (\delta G_M(1))_{ab} \\ &= (2/\pi) \mathcal{Q}(D) \{ (1 + D^2) \tan^{-1}(1/D) - D \}. \end{aligned} \quad (7.13)$$

Here "max" means "the larger term of".

In case when we use the form (a) in $X \geq D$,

the maximum estimation of $(\delta C_{Nw})_{at}$ is calculated by (7.6) and (7.13) taking $\mathcal{Q}_b(X)$ in place of $\mathcal{Q}_t(X)$. If we denote this by $|(\delta C_{Nw})_{at}|_{\max}$, we have

$$\begin{aligned} |(\delta C_{Nw})_{at}|_{\max} &= (\delta C_{Nw})_{ab} \\ &= (4/3)N^2\mathcal{Q}(D)(1-0.095r^2) \\ &\quad \times \{(1+D^2)\tan^{-1}(1/D)-D\} \\ &= \frac{8}{9}N^2\frac{\mathcal{Q}(D)}{D}(1-0.095r^2)\left(1-\frac{1}{5}\frac{1}{D^2}+\dots\right). \end{aligned} \quad (7.14)$$

The last expansion holds provided $D > 1$.

In case when the form (c) is used in $X \geq D$, we have, by (7.11), (7.12), (7.6) and (7.13),

$$\begin{aligned} |(\delta C_{Nw})_{ct}|_{\max} &= \tan^{-1}(1/D)\{(1+D^2)\tan^{-1}(1/D)-D\}^{-1}(\delta C_{Nw})_{ab} \\ &\approx 1.5|(\delta C_{Nw})_{at}|_{\max}. \end{aligned} \quad (7.15)$$

(3) *Application.* We shall examine the results in §5 by the above formulae, treating three cases where $\mathcal{Q}_E(X)$ in the free streamline range, $X \leq D$, is given by the elliptic hodograph $\mathcal{Q}_L(X)$, the Woods type $\mathcal{Q}_W(X)$ and the experimental curve $\mathcal{Q}_{exp}(X)$, respectively. We cut off the data given by the above examples in the range $X \geq D$ and treat this range as the mixing range, where we use the form (a) in place of $\mathcal{Q}_t(X)$, so that the maximum deviation of C_{Nw} , i.e. $|(\delta C_{Nw})_{at}|_{\max}$, is

Fig. 7. $|(\delta C_{Nw})_{at}|_{\max}$ vs. $(x)D$. The marks on the curve show the relation $x(D)$ for $D=1, 2, 3$ and 4. The symbols used in the figure are explained in Table I.

given by (7.14). Fig. 7 shows the relation of $|(\delta C_{Nw})_{at}|_{\max}$ versus $x(D)$, from which it will be seen that $|(\delta C_{Nw})_{at}|_{\max}$ is mainly affected by $\mathcal{Q}(D)/D$.

For example, we shall estimate the total error involved in the calculation of $\mathcal{Q}_{exp}^{II}(X)$. We have $x^{II}(D^{II})=1.085$ as shown in Table II so that $|(\delta C_{Nw})_{at}|_{\max} \approx 1.1 \times 10^{-2}$ by Fig. 7. Furthermore, by the result of §6 (3), $(\Delta C_{Nw})^{II} \approx 1 \times 10^{-3}$. The total error can be approximately estimated to be the sum of these two, namely 1.2×10^{-2} .

The range $0 \leq x \leq x_{nec}(D)$ of the free streamline is referred to as the "necessary free streamline range" on which $C_p(x)$ must be obtained to determine C_{Nw} within permissible experimental error. In case when $C_{p,exp}(x)$ is used in $x \leq x(D)$ and $\mathcal{Q}_a(X)$ is used in $X \geq D$, the value $x_{nec}(D)$ is determined by the use of Fig. 7. For example, when the experimental error of C_{Nw} is 1×10^{-2} or 1×10^{-3} , $x_{nec}(D)$ is given by 1.2 or 2.3. It is of interest to examine experimentally whether the so-estimated necessary free streamline range may be regarded as a free streamline range or not.

So far we have postulated the simplest limitation to $\mathcal{Q}_t(X)$: $0 \leq \mathcal{Q}_t(X) \leq \mathcal{Q}_E(D)$. If $\mathcal{Q}_t(X)$ in $X \geq D$ combined with $\mathcal{Q}_E(X)$ in $X \leq D$ is considered to satisfy the condition of finite width (3.14), the choice of $\mathcal{Q}(X)$ in $X \geq D$ can be severely limited, so that x_{nec} may be shortened appreciably. It is clear that even the rough knowledge of the damping behaviour of $\mathcal{Q}(X)$ less than about $0.3\mathcal{Q}(0)$ or that of $C_p(x)$ in $x=1 \sim 3$ is very useful to estimate C_{Nw} .

In general, if we use the Woods type $\mathcal{Q}_W(X)$ for the first approximation of $\mathcal{Q}(X)$ and choose adequately D and $\mathcal{Q}(X)$ in $X \geq D$ ($x_{nec}(D)$ being able to be estimated by the use of $\mathcal{Q}^{II}(X)$ and $x^{II}(X)$), it may not be necessary in many cases to carry out the third approximation for practical purpose to determine C_{Nw} from the observed data of $C_{pE}(x)$.

(4) *Examination of the experimental curve* $\mathcal{Q}_{exp}(x)$ used in §5. We see from Table I that the calculated value of C_{Nw} is larger by 4×10^{-3} than the experimental value. We examine the errors involved in the calculation of C_{Nw}^{III} . First, when we use $x(D)=2.3$, $|(\delta C_{Nw})_{at}|_{\max}$ decreases to 1×10^{-3} as explained above. Taking $D^{(III)}$, which has been determined by $x^{III}(D^{(III)}) \approx 2.3$ in place of $D^{(II)}$,

the new $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$, i.e. $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$, becomes smaller than $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$ in $X \geq D^{\text{III}}$ (cf. Fig. 1). Hence C_{NW} increases by the result of § 6 (2). Secondly, by the result of § 6 (3) $(\Delta e_{C_{\text{NW}}})^{\text{III}, \infty} \approx 1 \times 10^{-4}$. Therefore the theoretical value of C_{NW} determined by the tentatively adopted $\mathcal{Q}_{\text{exp}}(x)$ is larger than the experimental value of C_{NW} . Their difference may be larger than permissible experimental error of C_{NW} .

Thus the experimental value of C_{NW} will be given correctly by pushing up $\mathcal{Q}_{\text{exp}}(x)$ in the free streamline range by the result of § 6 (2). Referring to § 1 we denote this correct $\mathcal{Q}(x)$ by $\mathcal{Q}_{\text{ER}}(x)$. Hence $\mathcal{Q}_{\text{ER}}(x)$ may recover more rapidly to zero at $X \approx D$ than does $\mathcal{Q}_{\text{exp}}(x)$ when it should satisfy (3.14), so that its behaviour approaches that given by the notched hodograph (cf. Fig. 3).

This improvement is appropriate concerning the condition (3.14): We try to choose, in place of $\mathcal{Q}_a^{\text{III}}(X)$, the form:

$$\mathcal{Q}(X) = \mathcal{Q}_{\text{E}}(D) \{ 1 - (\mathcal{Q}_{\text{E}}'(D)/\mathcal{Q}_{\text{E}}(D))(X - D) + b^2(X - D)^2 \}^{-1}, \tag{7.16}$$

where $\mathcal{Q}'(X) = d\mathcal{Q}(X)/dX$, as the form of $\mathcal{Q}(X)$ in $X \geq D$ to continue to $\mathcal{Q}_{\text{E}}(X)$ in $X \leq D$ smoothly at $X = D$, and determine the constant b so as to satisfy (3.14). Then it can be shown that b is unreasonably small in the case of $\mathcal{Q}_{\text{exp}}^{\text{III}}(X)$ because of the too small value of $\int_0^{D^{\text{III}}} \mathcal{Q}_{\text{exp}}^{\text{III}}(X^*) dX^*$. But, in the case of $\mathcal{Q}_{\text{ER}}(x)$, b may take a reasonable value and we may treat $\mathcal{Q}_{\text{ER}}(x)$ to satisfy (3.14).

We examine the width of the free streamlines at about $x = 1.5 \sim 2$ which we denote by d'' (cf. § 8 (2c)). From the comparison of various $\mathcal{Q}(X)$ in Fig. 1 and the corresponding values of d'' we may expect that d'' determined by $\mathcal{Q}_{\text{ER}}(x)$ (in this case $d'' \approx d'$) approaches the width of Kármán vortex street which has been observed as 1.475 by Fage and Johansen⁴⁾ (cf. Table II in ref. 3).

§ 8. Effect of the Deviation of $\mathcal{Q}(X)$ on the Free Streamline

(1) *General formulae.* (1a) In order to examine the effect of the deviation of $\mathcal{Q}(X)$ on the free streamline, we first examine the behaviour of $H(X)$ in the regions $X \ll 1$, $X \approx 1$ and $X \gg 1$. In $X \ll 1$ we may approximate $H(X)$ by (3.17) as stated in § 3 (3) so

that
$$H(X) \approx \ln q_s \cdot bX, \quad (X \ll 1). \tag{8.1}$$

We illustrate this relation: In the cases of $\Omega_{\text{L}}(X)$, $\Omega_{\text{W}}(X)$, $\Omega_{\text{exp}}^{\text{III}}(X)$ and $\Omega_{\text{K}}(X)$ [$\equiv 0$] the values of $H'(0)$, i.e. $dH(X)/dX$ at $X=0$ are $b \ln q_s = 0.52$, $(\ln q_s)^2 = 0.18$ (both by (3.19)), 0.10 (by numerical calculation) and 0 respectively.

From (3.10), putting $X^* = X(1-t)$ in $0 \leq X^* \leq X$ and $X^* = X(1-t)^{-1}$ in $X \leq X^* \leq \infty$, we have

$$H(X) = (2/\pi) \int_0^1 \{ \mathcal{Q}(X(1-t)) - \mathcal{Q}(X(1-t)^{-1}) \} \times (2t - t^2)^{-1} dt.$$

If $\mathcal{Q}(X^*)$ is analytic in $|X^* - X| \leq k$, k being a constant, $\mathcal{Q}(X(1-t)) - \mathcal{Q}(X(1-t)^{-1})$ can be expanded in power series of t in the range of $t \leq t_0$ where we choose t_0 less than both kX^{-1} and $k(1+X)^{-1}$, so that

$$H(X) = \frac{2}{\pi} \left\{ \int_0^{t_0} \frac{-2\mathcal{Q}'(X)X - \mathcal{Q}''(X)Xt + O(t^2)}{2-t} dt + \int_0^{t_0} \frac{\mathcal{Q}(Xu) - \mathcal{Q}(Xu^{-1})}{1-u^2} du \right\},$$

where we have put $t = 1 - u$ in $t_0 \leq t \leq 1$. By rough estimation of this equation we have

$$H(X) \approx \frac{2}{\pi} \left\{ - \left(4 \ln \frac{2}{2-t_0} - t_0 \right) \mathcal{Q}'(X)X + \mathcal{Q}(0)(1-t_0) \right\}. \tag{8.2}$$

Hence $H(X)$ is large when $\mathcal{Q}'(X)$ and X are large. This formula may be useful for moderate X .

The maximum value of $H(X)$ and the corresponding value, X_h , of X in the case of $\Omega_{\text{L}}(X)$ and $\Omega_{\text{W}}(X)$ are found, by (3.17), to be $H(X_h) = (\ln q_s)/2 = 0.218$, $X_h = b^{-1} = 0.83$ and $H(X_h) = 0.218$, $X_h = 2.30$ respectively, while in the cases of $\Omega_{\text{exp}}^{\text{II}}(X)$ and $\Omega_{\text{exp}}^{\text{III}}(X)$ we find, by numerical calculations, that $H(X_h) = 0.365$, $X_h = 2.68$ and $H(X_h) = 0.388$, $X_h = 2.79$ respectively. The large discrepancies between these values are due to the large deviation of $\Omega'(X)$ near $X \approx 2.5$ (Fig. 1).

Using (3.9), we have, for large X ,

$$\theta(X) = -H(X) + X^{-1} - (1/3)X^{-3} + \dots,$$

so that, using (3.12), the condition of finite width (3.14) can be replaced by

$$H(X) = X^{-1} + O(X^{-n}), \quad (n > 2, X \gg 1). \tag{8.3}$$

When (3.13) is satisfied, the coefficient of X^{-1} in (8.3) is less than unity or $H(X) \leq O(X^{-2})$.

For example, using (3.17), we have $H(X) \approx \ln q_s \times b^{-1}X^{-1}$ in $X \gg 1$ in the case (3.15) and using (3.18), we find that $\ln q_s \cdot b^{-1} < 1$ when (3.13) is

satisfied. In the Kirchhoff flow $H(X)=0$.

(1b) When $X \ll 1$, we have, by (3.9) and (8.1), $\sin \theta \approx 1$ and $\cos \theta \approx (1+H'(0))X$, so that

$$x(X) \approx Nq_s^{-1}(1+H'(0))X^3/3, \quad (8.4)$$

$$y(X) \approx Nq_s^{-1}X^2/2, \quad (8.5)$$

and therefore

$$y(X) \approx (N/q_s)^{1/3} 2^{-13/3} (1+H'(0))^{-2/3} x^{2/3}. \quad (8.6)$$

Hence we have $y \propto x^{2/3}$ irrespective of $\mathcal{Q}(X)$, and the rise of $y(x)$ near the separation point ($x=0$) is smaller, the larger is $H'(0)$. ($(N/q_s)^{1/3}$ is less sensitive to $\Delta\mathcal{Q}(X)$ than $H'(0)$.)

(1c) We next estimate $\Delta x(X)$. Using (3.11) we have

$$d(\Delta x(X)) = \{-\Delta\mathcal{Q}(X) + \Delta N/N + \Delta H(X) \tan \theta\} \times dx(X). \quad (8.7)$$

In the range $X \ll 1$, we have, using (3.9), $\Delta H(X) \tan \theta \approx H'(0)(1+H'(0))$ and it can be verified that $\Delta H(X) \tan \theta$ is the main term in the brackets of (8.7) when $X \ll 1$. But, by (8.7), $\Delta x(X)$ is small in $X \ll 1$ for $dx(X) \propto X^2 dX$.

Let X_A be the value of X at a point where $|\Delta\mathcal{Q}(X)|$ becomes maximum. Then, in the range $X \approx X_A$ we can verify that $\Delta\mathcal{Q}(X)$ becomes the main term in (8.7) when q_s is unchanged. Therefore

$$\Delta x(X) \approx -x \overline{\Delta\mathcal{Q}}(X), \quad (X \approx X_A), \quad (8.8)$$

where $\overline{\Delta\mathcal{Q}}(X)$ is a weighted mean:

$$\overline{\Delta\mathcal{Q}}(X) = \left\{ \int_0^X \Delta\mathcal{Q}(X) dx(X) \right\} / x(X). \quad (8.9)$$

Hence for positive $\Delta\mathcal{Q}(X)$ at $X \approx X_A$, $\Delta x(X)$ is negative there, $\Delta x(X)$ for moderate X ($X=1 \sim 4$ or $x=0.2 \sim 2$) may be at most of the order of $\Delta\mathcal{Q}(X_A)$ when q_s is unchanged so that it is small in general.

In the range where $\Delta\mathcal{Q}(X)$ becomes small, $\Delta N/N$ predominates in (8.7). For positive $\Delta\mathcal{Q}(X)$ at $X \approx X_A$, ΔN is positive (cf. § 6 (2)) so that negative $\Delta x(X)$ which appeared at $X \approx X_A$ begins to decrease in the range where $\Delta\mathcal{Q}(X)$ becomes small.

(1d) Lastly, we shall estimate $\Delta y(X)$ for moderate X . Using (3.12) we have

$$d(\Delta y(X)) = \{-\Delta\mathcal{Q}(X) + \Delta N/N + \Delta H(X) \cot \theta\} \times dy(X). \quad (8.10)$$

$\Delta H(X) \cot \theta$ is negligible for $X \ll 1$, but it can be large at moderate X (cf. (1a)), so that $\Delta y(X)$ can be large at moderate X (cf. Fig. 2). For further discussion on $\Delta y(X)$, see (2c).

(2) *General results.* (2a) First we prove

roughly the rapid convergency of successive approximations prescribed in § 4. By its definition together with (8.10), $(\Delta\mathcal{Q}(X))^{N, N+1}$ is estimated to be

$$\begin{aligned} (\Delta\mathcal{Q}(X))^{N, N+1} &= \mathcal{Q}_E(x^{N-1}(X)) - \mathcal{Q}_E(x^N(X)) \\ &\approx \frac{d\mathcal{Q}_E(x^{N-1}(X))}{dx^{N-1}(X)} (\Delta x)^{N-1, N} \\ &\approx \frac{d\mathcal{Q}^N(X)}{dX} \frac{dX}{dx^{N-1}(X)} x^{N-1}(X) (\overline{\Delta\mathcal{Q}}(X))^{N-1, N}. \end{aligned} \quad (8.11)$$

Hence $(\Delta\mathcal{Q}(X))^{N, N+1}$ decreases appreciably in $x \approx 0$. For moderate x , we estimate this equation at $x=1$ by taking $\mathcal{Q}_{\text{exp}}(X)$ as $\mathcal{Q}_E(X)$. From Figs. 1 and 2, we find $-d\mathcal{Q}_{\text{exp}}(X)/dX \approx 0.3$ and $dX/dx \approx 1.4$, so that

$$(\Delta\mathcal{Q}(X))^{N, N+1} \approx 0.4 (\overline{\Delta\mathcal{Q}}(x))^{N-1, N}. \quad (8.12)$$

Therefore, when q_s is unchanged, $(\Delta\mathcal{Q}(X))^{N, N+1}$ at $x \approx 1$ becomes much smaller than $(\Delta\mathcal{Q}(X))^{N-1, N}$. By (8.12) we can explain the fact in § 6 (3) that $(\Delta C_{Nw})^{N, N+1}$ is about $0.1 \times (\Delta C_{Nw})^{N-1, N}$.

(2b) In case when $\mathcal{Q}(X)$ has a deviation, $\delta\mathcal{Q}(X)$, only in $X \geq D$, the deviation $\delta x(X)$ of $x(X)$ is especially small in $X < D$, since $[\overline{\Delta\mathcal{Q}}(X)=0$ in $X \leq D$. By (7.6) and (7.7) $\delta N/N \approx 0.4 N^{-2} \delta C_{Nw}$ so that $\delta N/N$ is small when D and $\delta\mathcal{Q}(X)$ are so chosen that δC_{Nw} is small. Therefore in $X < D$ a small $\delta x(X)$ may appear, if possible, only in the neighbourhood of $X=D$ by (8.7).

(2c) Lastly we consider the width between the free streamlines. We take $\mathcal{Q}(X)$ which satisfies the condition of finite width (3.14). If we push down (or up) $\mathcal{Q}(X)$, the left-hand side of (3.14) becomes smaller (or greater) than $\pi/2$, so that the width between the free streamlines at infinity, $1+2y(\infty)$, becomes $+\infty$ (or $-\infty$). Therefore, if we combine properly these modifications of $\mathcal{Q}(X)$ and keep $\mathcal{Q}(X)$ to satisfy (3.14), we can make $1+2y(\infty)$ to take an arbitrary value, e.g. zero or the width of Kármán vortex street. Moreover, since, as will be seen from (7.6) and (7.1) (cf. Fig. 7), $\delta\mathcal{Q}(X)$ in $X \geq D$ has little effect upon C_{Nw} , the effect of these modifications of $\mathcal{Q}(X)$ upon C_{Nw} can easily be made within experimental error. Hence, instead of $1+2y(\infty)$, only d'' in § 7 (4) is significant in the experimental relation to C_{Nw} .

(3) *Application.* We shall apply the above results in (1) to the results in § 5. (3a) At

$x \approx 0$, the rise of the curve $y(x)$ of the free streamline is in the order of the cases of $\mathcal{Q}_L(X)$, $\mathcal{Q}_W(X)$, $\mathcal{Q}_{\text{exp}^{III}}(X)$ and $\mathcal{Q}_K(X)$ (the last case being the largest) (see Fig. 5). This can be explained from the value of $H'(0)$ in (1a).

(3b) We see that $X_A=1\sim 2$ in each case of Fig. 1. Corresponding to this, remarkable but small $\Delta x(X)$ of the order of $\Delta \mathcal{Q}(X_A)$ appears at $X \approx X_A$ in Fig. 2. As will be seen in Fig. 2, $\Delta x(X)$ at $X \approx 3$ tends to decrease by the effect of ΔN .

(3c) In the examples in (1a), $\Delta H(X) \cot \theta$ is large in $X=2.5\sim 3$ so that it makes a large contribution to $\Delta y(X)$ there (Fig. 2). Thus, in order to determine the shape of the free streamline in the free streamline range it is desirable to choose $\mathcal{Q}(X)$ in $X \geq D$ in such a manner that the gradient at $X=D$ is continuously connected, e.g. like the form (7.16). In this way the shape in this range may be determined within experimental error. To know the damping behaviour of $C_p(x)$ in $X \approx D$ (e.g. $x=1\sim 3$), even if it is rough, is very useful not only to determine C_{Nw} but also to find the shape of the free streamline.

§ 9. Effect of the Separation Velocity and the Condition of Finite Width upon δC_{Nw}

Using the formulae in §§ 6~8, it is easy to estimate quantitatively the change of Δr ,

$\Delta x(X)$, etc. when $\mathcal{Q}_E(X)$ in $X \leq D$ is changed by the decrease of q_s ($q_s=1.545$ may be extremely large value observed in experiment, cf. the data of Roshko⁶⁾). But we only illustrate here the effect of the decrease of q_s upon $|(\delta C_{Nw})_{\text{at}|_{\text{max}}}$ in Fig. 7 in which $\mathcal{Q}_E(X)$ in $X \leq D$ is given by the Woods type (3.19) and q_s takes 1.3 and 1.1 other than 1.545.

$|(\delta C_{Nw})_{\text{at}|_{\text{max}}}$ in the case where the condition of finite width (3.14) is not satisfied is illustrated in Fig. 7 where $\mathcal{Q}_E(X)$ in $X \leq D$ is given by the case of the elliptic hodograph (5.1). In the Kirchhoff flow ($q_s=1$), $\delta C_{Nw}=0$. In general, it may be easily verified, using the formulae in §§ 6~8, that in case when (3.13) is satisfied the necessary free streamline range becomes longer when it is pushed up to satisfy (3.14).

Appendix I

In Table IV the accuracy of the approximate formulae (6.6) and (6.8) is examined for the cases of $\mathcal{Q}_L(X)$, $\mathcal{Q}_W(X)$, $\mathcal{Q}_{\text{exp}^{II}}(X)$ and $\mathcal{Q}_{\text{exp}^{III}}(X)$. The first column shows the value of r defined by (6.3). The second column shows ϵ_{max} which denotes the value of $\epsilon(W)$ corresponding to maximum $|\epsilon(W)|$ (hence, when ϵ_{max} is negative, it means the minimum value of $\epsilon(W)$). It is found that the slower $\Omega(X)$ recovers to zero, the smaller become r and $|\epsilon_{\text{max}}|$. This tendency can be seen by the use of (6.1). The third and the fourth columns show the ratios of the approximate values of N and $1-C_{Nw}$

Table IV. The accuracy of the approximate formulae (6.6) and (6.8).

	r	ϵ_{max}	$\frac{N_{\text{appr}}}{N} - 1$	$\frac{1 - C_{Nw \text{appr}}}{1 - C_{Nw}} - 1$
L	0.26780	-3.9×10^{-2}	1.3×10^{-2}	4.4×10^{-2}
W	0.14096	-1.1×10^{-2}	3.5×10^{-3}	1.0×10^{-2}
exp ^{II}	0.09748	-5.0×10^{-4}	9.7×10^{-4}	1.3×10^{-3}
exp ^{III}	0.09581	-5.7×10^{-4}	2.4×10^{-4}	5.1×10^{-4}

respectively, which are obtained by (6.6) and (6.8). The values in the third and the fourth columns should be compared to $(1 + \epsilon_{\text{max}})^{-1} - 1$ and $(1 + \epsilon_{\text{max}})^{-2} - 1$ respectively. It may be said that the accuracy of the approximate formulae (6.6) and (6.8) is sufficient.

Appendix II

We estimate the value of $\epsilon_M(W)$ in (7.2) when $|\epsilon_M(W)|$ becomes maximum. We denote this by $\epsilon_{M \text{max}}$ (the negative $\epsilon_{M \text{max}}$ is the minimum value of $\epsilon_M(W)$). To estimate the order of $\epsilon_{M \text{max}}$, we put, e.g. $\Omega(D)=0.15$ and $D=2$. Then $\epsilon_{M \text{max}}$ becomes

1.0×10^{-3} and 6.7×10^{-4} in the cases of the forms (a) and (b) respectively. Therefore the approximation $\epsilon_M(W)=0$ in (7.2) is a good one.

In a practical problem, noting the order of the quantities r , $|\epsilon_{\text{max}}|$ and $|\delta \epsilon_{M \text{max}}|$, the last one being of the order of $|\epsilon_{M \text{max}}|$, the maximum error ratio for the approximate formulae (7.6) and (7.7) may not exceed 5×10^{-2} even in the worst condition. For the purpose to estimate the necessary free streamline range x_{noc} by the use of Fig. 7 this rough error estimation is sufficiently enough.

On the Acoustic Field by a Vibrating Source Arbitrarily Distributed on a Ribbon Plate. I

By Norio KAWAI

Department of Physics, Tôkyo Institute of Technology

(Received June 25, 1958)

Two-dimensional rigorous solutions are presented for the acoustic field in the air caused by the vibrating source arbitrarily distributed on an infinitely thin and infinitely long ribbon. Using rectangular coordinates, the unique solution satisfying the boundary condition is obtained by the method of expansion in the hypergeometric polynomials. The expression of the velocity potential at large distance, pressure on the ribbon plate and power of radiation are obtained as a function of $k=2\pi a/\lambda$, where a is the half-breadth of the plate and λ is the wave length.

§ 1. Introduction

The calculation of the acoustic field caused by an emitter with a baffle of infinite dimensions can be carried out by the Rayleigh formula, and various problems for such emitters have been solved. So far as we are aware, however, there have been rather few treatises on the acoustical radiation of an emitter vibrating freely or with a baffle of finite dimensions; only the general theories^{7), 8), 9)} with respect to such problems and the calculations of examples for a circular plate source are treated, but no example for a ribbon source.

Our method of calculation is applicable to the case of an emitter with a finite or an infinite baffle, and also to the calculation of the diffracted waves by a ribbon plane which is fixed or vibrating.

As a rule, the elliptic cylindrical coordinates are used for problems concerning the domain outside an infinitely thin and infinitely long ribbon plate, the method of integral equation or other methods⁹⁾ are used, but those are still far from convenient for numerical computation. In the present paper we use the

rectangular cartesian coordinates for the same problem. That is, we express the wave equation in the rectangular coordinates and express the solution of the wave equation in terms of modified Weber-Schafheitlin integrals.

The arbitrary constants in the expression of the velocity potential are determined by the method of expansion in hypergeometric polynomials.

In the forgoing papers¹⁾, we applied this method to the calculation of the field caused by a vibrating source arbitrarily distributed on a circular plate, and discussed as an example the radiation of sound wave from a vibrating plane circular plate with a fixed circular baffle²⁾. The expression of the field for a ribbon plate has the factors $G_{nv}^{1/2}$ and $G_{nv}^{-1/2}$, whereas the former calculation for a circular plate have the factor G_{nv}^m , where m is an integer. G_{nv}^m with integer m are tabulated in the paper, "Acoustic field by a vibrating source arbitrarily distributed on a plane circular disc"¹⁾ which is referred to as *A* in the present paper. Tables of $G_{nv}^{1/2}$ and $G_{nv}^{-1/2}$ are to be published in the next report II.

We refer to the paper, "Diffraction of electromagnetic waves by ribbon and slit"⁵⁾ as *B*.

§ 2. General Solution

Taking *X* and *y* axes on the ribbon plate and *Z* axis normal to the plate, we use *X*, *y*, *Z* as the rectangular coordinates of a point. Further we set $x=X/a$, $\rho=y/a$ and $z=Z/a$, where *a* is the half-breadth of the plate.

When the velocity potential of the acoustic field is expressed by $\Phi \exp(i\omega t)$, Φ must satisfy the following wave equation

$$\frac{\partial^2 \Phi}{\partial \rho^2} + \frac{\partial^2 \Phi}{\partial z^2} + k^2 \Phi = 0, \tag{1}$$

where $k=(\omega/c)a=(2\pi/\lambda)a$, *c* is the propagation velocity and λ is the wave length of sound.

Since the field is antisymmetric with respect to the plane $z=0$, the condition

$$\Phi=0 \tag{2}$$

must hold for $z=0$ and $|\rho|>1^*$.

We can use the following expression, as a solution of (1) satisfying the condition (2),

Fig. 1.

$$\begin{aligned} \Phi = & \mp \sqrt{\rho} \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \int_0^{\infty} \frac{J_{1/2}(\rho \xi) J_{(1/2)+2n+(3/2)}(\xi)}{\sqrt{\xi}} \exp(\mp \sqrt{\xi^2 - k^2} z) d\xi \right. \\ & \left. + A_n^{-1/2} \int_0^{\infty} \frac{J_{-1/2}(\rho \xi) J_{-(1/2)+2n+(3/2)}(\xi)}{\sqrt{\xi}} \exp(\mp \sqrt{\xi^2 - k^2} z) d\xi \right\}, \end{aligned} \tag{3}$$

taking the upper sign for $z>0$ and the lower sign for $z<0$.

The integrals in the bracket are modified Weber-Schafheitlin integrals, and have the property to become zero for $|\rho| \geq 1$ or $|y| \geq a$ when $z=0^0$, and the formula (3) means that $\partial \Phi / \partial z$ is continuous at $z=0$. The first integral having subscript 1/2 is an odd solution and the second integral having subscript -1/2 is an even solution of ρ respectively.

The coefficients $A^{1/2}$ and $A^{-1/2}$ are to be determined by the velocity distribution on the ribbon plate,

$$\begin{aligned} -\frac{1}{a} \left(\frac{\partial \Phi}{\partial z} \right)_{z=0} &= v \text{ (Vibration velocity of each point on the plate)} \\ &\equiv \frac{1}{a} f(\rho) \quad \text{for } |\rho| < 1, \end{aligned} \tag{4}$$

and $f(\rho)$ can be expressed as the sum of an even function $f_e(\rho)$ and odd function $f_o(\rho)$; that is $f(\rho)=f_e(\rho)+f_o(\rho)$,

Using the hypergeometric polynomials

$$\begin{aligned} v_n^m(x) &= x^{-m/2} \int_0^{\infty} \sqrt{\xi} J_m(\sqrt{x} \xi) J_{m+2n+(3/2)}(\xi) d\xi \\ &= \frac{\sqrt{2} \Gamma(m+n+\frac{3}{2})}{n! \Gamma(m+1)} F\left(m+n+\frac{3}{2}, -n, m+1, x\right) \\ &= \frac{\sqrt{2} \Gamma(m+n+\frac{3}{2})}{m! \Gamma(m+n+1)} x^{-m(1-x)^{-1/2}} \frac{d^n}{dx^n} \{x^{m+n}(1-x)^{n+(1/2)}\}^{**}, \quad (0 \leq x \leq 1) \end{aligned} \tag{5}$$

* This condition means that the pressure is zero or unchanged from an undisturbed state. Or this condition is derived from the consideration that the velocity potential due to a linearly vibrating point source has the value zero on the plane through that source and perpendicular to the vibration of source, and that the vibrating source on the plane is an ensemble of such point sources.

** $v_n^{-1/2}(x)$ are used for the expansion of even functions and $v_n^{1/2}(x)$ are used for odd functions.

an arbitrary function $f(x)$ can be expanded into the following series

$$f(x) = \sum_{n=0}^{\infty} B^{(n)} v_n^m(x), \quad (6)$$

where

$$B^{(n)} = \frac{m+2n+\frac{3}{2}}{\sqrt{2} \Gamma(n+\frac{3}{2})} \int_0^1 f(x) \frac{d^n}{dx^n} \{x^{m+n}(1-x)^{n+(1/2)}\} dx^*, \quad (7)$$

By the above theorem, the following relations are obtained,

$$f_e(\sqrt{x}) = \sum_{n=0}^{\infty} a_n^{-1/2} v_n^{-1/2}(x),$$

where

$$a_n^{-1/2} = \frac{2n+1}{\sqrt{2} \Gamma(n+\frac{3}{2})} \int_0^1 f_e(\sqrt{x}) \frac{d^n}{dx^n} \{x^{n-(1/2)}(1-x)^{n+(1/2)}\} dx;$$

$$f_0(\sqrt{x}) = \sqrt{x} \sum_{n=0}^{\infty} a_n^{1/2} v_n^{1/2}(x),$$

where

$$a_n^{1/2} = \frac{2n+2}{\sqrt{2} \Gamma(n+\frac{3}{2})} \int_0^1 f_0(\sqrt{x}) x^{-1/2} \frac{d^n}{dx^n} \{x^{n+(1/2)}(1-x)^{n+(1/2)}\} dx. \quad (8)$$

Writing $\rho = \sqrt{x}$, we have

$$\begin{aligned} \left(\frac{\partial \Phi}{\partial z} \right)_{z=0} &= \sqrt{\rho} \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \int_0^{\infty} \frac{J_{1/2}(\rho \xi) J_{(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi \right. \\ &\quad \left. + A_n^{-1/2} \int_0^{\infty} \frac{J_{-1/2}(\rho \xi) J_{-(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi \right\} \\ &= x^{1/4} \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \int_0^{\infty} \frac{J_{1/2}(\sqrt{x} \xi) J_{(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi \right. \\ &\quad \left. + A_n^{-1/2} \int_0^{\infty} \frac{J_{-1/2}(\sqrt{x} \xi) J_{-(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi \right\} \end{aligned} \quad (9)$$

By the aid of the expansion formula

$$x^{-m/2} J_m(p\sqrt{x}) = \left(\frac{p}{2} \right)^m \sum_{s=0}^{\infty} \frac{(-1)^s (p\sqrt{x}/2)^{2s}}{s! \Gamma(m+s+1)}$$

and the equations (6) and (7), we get

$$J_m(p\sqrt{x}) = x^{m/2} \sum_{n=0}^{\infty} (2m+4n+3) \frac{J_{m+2n+(3/2)}(p)}{p^{3/2}} v_n^m(x)^{**}. \quad (10)$$

Using (10)

$$x^{1/4} \int_0^{\infty} \frac{J_m(\sqrt{x} \xi) J_{m+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi = x^{(2m+1)/4} \sum_{\nu=0}^{\infty} (2m+4\nu+3) G_{n\nu}^m v_{\nu}^m(x), \quad (11)$$

where

$$G_{n\nu}^m = \int_0^{\infty} \frac{(\xi^2 - k^2)^{1/2} J_{m+2n+(3/2)}(\xi) J_{m+2\nu+(3/2)}(\xi)}{\xi^2} d\xi. \quad (12)$$

* Reference (6), P. 203 and P. 209, 210.

** See the paper B, P. 193, (2.14), and reference (4) P. 301.

Then, by (11)

$$x^{1/4} \int_0^\infty \frac{J_{1/2}(\sqrt{x\xi}) J_{(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi = x^{1/2} \sum_{\nu=0}^\infty (4\nu+4) G_{n\nu}^{1/2} v_\nu^{1/2}(x) \quad (13)$$

for $m=1/2$ (odd), and

$$x^{1/4} \int_0^\infty \frac{J_{-1/2}(\sqrt{x\xi}) J_{-(1/2)+2n+(3/2)}(\xi) \sqrt{\xi^2 - k^2}}{\sqrt{\xi}} d\xi = \sum_{\nu=0}^\infty (4\nu+2) G_{n\nu}^{-1/2} v_\nu^{-1/2}(x) \quad (14)$$

for $m=-1/2$ (even).

Therefore

$$\left(\frac{\partial \Phi}{\partial z} \right)_{z=0} = \sum_{n=0}^\infty \left\{ A_n^{1/2} x^{1/2} \sum_{\nu=0}^\infty (4\nu+4) G_{n\nu}^{1/2} v_\nu^{1/2}(x) + A_n^{-1/2} \sum_{\nu=0}^\infty (4\nu+2) G_{n\nu}^{-1/2} v_\nu^{-1/2}(x) \right\}. \quad (15)$$

Substituting (8) and (15) into the equation (4), and equating the even term in the left-hand side to the even term in the right-hand side and the odd term to the odd term respectively, we obtain

$$\begin{aligned} - \sum_{n=0}^\infty A_n^{1/2} x^{1/2} \sum_{\nu=0}^\infty (4\nu+4) G_{n\nu}^{1/2} v_\nu^{1/2}(x) &= \sqrt{x} \sum_{\nu=0}^\infty a_\nu^{1/2} v_\nu^{1/2}(x) \\ - \sum_{n=0}^\infty A_n^{-1/2} \sum_{\nu=0}^\infty (4\nu+2) G_{n\nu}^{-1/2} v_\nu^{-1/2}(x) &= \sum_{\nu=0}^\infty a_\nu^{-1/2} v_\nu^{-1/2}(x). \end{aligned}$$

Then we can set

$$\begin{aligned} \sum_{s=0}^\infty A_s^{1/2} G_{sn}^{1/2} &= -a_n^{1/2}/(4n+4), & \sum_{s=0}^\infty A_s^{-1/2} G_{sn}^{-1/2} &= -a_n^{-1/2}/(4n+2) \\ & & (n=0, 1, 2, 3, \dots). \end{aligned} \quad (16)$$

Introducing $X_{n\nu}^m$ by the follows relations

$$\sum_{s=0}^\infty G_{sn}^m X_{s\nu}^m = -\delta_{n\nu} \quad \left(m = \frac{1}{2} \text{ or } -\frac{1}{2} \right), \quad (17)$$

where $\delta_{n\nu}=1$ as $\nu=n$ and $\delta_{n\nu}=0$ as $\nu \neq n$, we can set that

$$A_n^{1/2} = \sum_{\nu=0}^\infty \frac{a_\nu^{1/2}}{4\nu+4} X_{n\nu}^{1/2}, \quad A_n^{-1/2} = \sum_{\nu=0}^\infty \frac{a_\nu^{-1/2}}{4\nu+2}. \quad (18)$$

The arbitrary coefficients $A_n^{1/2}$ and $A_n^{-1/2}$ in the expansion formula (3) are thus determined.

§ 3. Calculation of $G_{n\nu}^m$ and $X_{n\nu}^m$ ($m=1/2, -1/2$)

For the calculation we express $G_{n\nu}^m$ as follows

$$G_{n\nu}^m = g_1(\alpha, \beta) + i g_2(\alpha, \beta), \quad (19)$$

where

$$\left. \begin{aligned} g_1(\alpha, \beta) &= \int_k^\infty \frac{\sqrt{\xi^2 - k^2}}{\xi^2} \frac{J_\alpha(\xi) J_\beta(\xi) d\xi}{\xi^2}, & g_2(\alpha, \beta) &= \int_0^k \frac{\sqrt{\xi^2 - k^2}}{\xi^2} \frac{J_\alpha(\xi) J_\beta(\xi) d\xi}{\xi^2} \\ \text{and} & & & \\ \alpha &= m+2n+\frac{3}{2}, & \beta &= m+2\nu+\frac{3}{2}. \end{aligned} \right\} \quad (20)$$

By the paper B,

$$\begin{aligned}
g_1(\alpha, \beta) = & \frac{\sqrt{\pi}}{4} \sum_{\mu=0}^{((\alpha+\beta)/2)-1} \frac{(-1)^\mu}{\mu!} \frac{\Gamma\left(\frac{\alpha+\beta}{2}-\mu\right) \Gamma(2\mu+1) \left(\frac{k}{2}\right)^{2\mu}}{\Gamma\left(\mu+1+\frac{\alpha-\beta}{2}\right) \Gamma\left(\mu+1+\frac{\beta-\alpha}{2}\right) \Gamma\left(\mu+1+\frac{\alpha+\beta}{2}\right) \Gamma\left(-\mu+\frac{3}{2}\right)} \\
& + (-1)^{((\alpha+\beta)/2)+1} \frac{\sqrt{\pi}}{4} \sum_{\mu=0}^{\infty} \frac{\Gamma(\alpha+\beta+2\mu+1) \left(\frac{k}{2}\right)^{\alpha+\beta+2\mu}}{\Gamma(\mu+1) \Gamma\left(\frac{\alpha+\beta}{2}+\mu+1\right) \Gamma(\alpha+\mu+1) \Gamma(\beta+\mu+1) \Gamma(\alpha+\beta+\mu+1) \Gamma\left(-\frac{\alpha+\beta}{2}-\mu+\frac{3}{2}\right)} \\
& \cdot \left\{ 2 \log \frac{k}{2} + 2\psi(\alpha+\beta+2\mu+1) - \psi(\mu+1) - \psi\left(\frac{\alpha+\beta}{2}+\mu+1\right) - \psi(\alpha+\beta+1) \right. \\
& \left. - \psi(\beta+\mu+1) - \psi(\alpha+\beta+\mu+1) + \psi\left(-\frac{\alpha+\beta}{2}-\mu+\frac{3}{2}\right) \right\}, \quad (21)
\end{aligned}$$

where $\phi(z) = (d/dz) \log \Gamma(z) = \Gamma'(z)/\Gamma(z)$, and by the paper A,

$$g_2(\alpha, \beta) = \frac{\sqrt{\pi}}{4} \sum_{\mu=0}^{\infty} \frac{(-1)^\mu \left(\frac{k}{2}\right)^{\alpha+\beta+2\mu} (\alpha+\beta+2\mu)! \Gamma\left(\frac{\alpha+\beta-1}{2}+\mu\right)}{\mu! (\alpha+\beta+\mu)! \Gamma(\alpha+\mu+1) \Gamma(\beta+\mu+1) \Gamma\left(\frac{\alpha+\beta}{2}+\mu+1\right)}. \quad (22)$$

Using the two formulae (21) and (22), we obtain the following results,

$$\begin{aligned}
G_{00}^{1/2} &= \frac{1}{4} - \frac{1}{12} \left(\frac{k}{2}\right)^2 + \left(\frac{1}{32} \log \frac{k}{2} + \frac{b_1}{64}\right) \left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + i \left\{ \frac{\pi}{64} \left(\frac{k}{2}\right)^4 + O(k^6) \right\} \\
G_{01}^{1/2} &= -\frac{1}{96} \left(\frac{k}{2}\right)^2 - \frac{1}{480} \left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + iO(k^6) \\
G_{11}^{1/2} &= \frac{1}{8} - \frac{1}{120} \left(\frac{k}{2}\right)^2 - \frac{1}{1920} \left(\frac{k}{4}\right)^4 + O(k^6 \cdot \log k) + iO(k^6) \\
G_{02}^{1/2} &= -\frac{1}{16 \cdot 6!} \left(\frac{k}{2}\right)^4 + O(k^6) + iO(k^6) \\
G_{12}^{1/2} &= -\frac{1}{480} \left(\frac{k}{2}\right)^2 - \frac{1}{2 \cdot 7!} \left(\frac{k}{2}\right)^4 + O(k^6) + iO(k^{10}) \\
G_{22}^{1/2} &= \frac{1}{12} - \frac{12}{7!} \left(\frac{k}{2}\right)^2 - \frac{36}{16 \cdot 8!} \left(\frac{k}{2}\right)^4 + O(k^6) + iO(k^{12}),
\end{aligned}$$

and

$$\begin{aligned}
G_{00}^{-1/2} &= \frac{1}{2} + \left(\frac{1}{2} \log \frac{k}{2} + \frac{a_2}{4}\right) \left(\frac{k}{2}\right)^2 - \left(\frac{1}{8} \log \frac{k}{2} + \frac{a_3}{16}\right) \left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) \\
&\quad + i \left\{ \frac{\pi}{4} \left(\frac{k}{2}\right)^2 - \frac{\pi}{16} \left(\frac{k}{2}\right)^4 + O(k^6) \right\}^* \\
G_{01}^{-1/2} &= -\frac{1}{24} \left(\frac{k}{2}\right)^2 + \left(\frac{1}{48} \log \frac{k}{2} + \frac{a_4}{96}\right) \left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + i \left\{ \frac{\pi}{96} \left(\frac{k}{2}\right)^4 + O(k^6) \right\} \\
G_{11}^{-1/2} &= \frac{1}{6} - \frac{1}{48} \left(\frac{k}{2}\right)^2 - \frac{1}{320} \left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + iO(k^6)
\end{aligned}$$

* $G_{n\nu}^{-1/2}$ is denoted by $G_{n\nu}^{*-1/2}$, and k by γ in the paper B. $\pi/48(\gamma/2)^4$ in the expression of $G_{00}^{*-1/2}$ (B. p. 196) is incorrect, and to be replaced $\pi/16(k/2)^4$.

$$\begin{aligned} G_{02}^{-1/2} &= -\frac{1}{1920}\left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + iO(k^6) \\ G_{12}^{-1/2} &= -\frac{1}{240}\left(\frac{k}{2}\right)^2 - \frac{1}{2880}\left(\frac{k}{2}\right)^4 + O(k^6) + iO(k^6) \\ G_{22}^{-1/2} &= \frac{1}{10} - \frac{1}{240}\left(\frac{k}{2}\right)^2 - \frac{1}{6720}\left(\frac{k}{2}\right)^4 + O(k^6) + iO(k^{10}), \end{aligned}$$

where

$$\begin{aligned} b_1 &= -\phi(1) - 3\phi(3) + \phi(5) + \phi(-\tfrac{1}{2}) = -0.6484 \\ a_2 &= -\phi(1) - 3\phi(2) + \phi(3) + \phi(\tfrac{1}{2}) = -1.7317 \\ a_3 &= -\phi(2) - 3\phi(3) - \phi(4) + 2\phi(5) + \phi(-\tfrac{1}{2}) = -1.3983 \\ a_4 &= -\phi(1) - \phi(2) - \phi(3) - \phi(4) + \phi(5) + \phi(-\tfrac{1}{2}) = -0.4817. \end{aligned}$$

The method of calculation of X_{nv}^m from G_{nv}^m is as follows*. We have

$$X_{nv}^m = \sum_{p=0}^\infty X_{nv}^{m(p)},$$

where

$$X_{nn}^{m(0)} = -\frac{1}{G_{nn}^m}, \quad X_{n'n}^{m(0)} = -\frac{G_{nn}^m}{G_{n'n}^m} X_{nn}^{m(0)} \quad (n' \neq n)$$

and

$$\begin{aligned} X_{nn}^{m(p)} &= -\frac{1}{G_{nn}^m} \sum_{s=0}^\infty X_{ns}^{m(p-1)} G_{sn}^m, \\ X_{n'n}^{m(p)} &= -\frac{G_{nn}^m}{G_{n'n}^m} X_{nn}^{m(p)} - \frac{1}{G_{n'n}^m} \sum_{s=0}^\infty X_{sn}^{m(p-1)} G_{sn'}^m, \quad (p=1, 2, 3, \dots) \end{aligned}$$

$\sum'$ denoting the omission of the terms $s=n$ and $s=n'$.

By the above mentioned method we obtain X_{nv}^m as follows,

$$\begin{aligned} -X_{00}^{1/2} &= 4 + \frac{4}{3}\left(\frac{k}{2}\right)^2 + \left(\frac{33}{72} - \frac{1}{2} \log \frac{k}{2} - \frac{b_1}{4}\right)\left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + i \left\{ -\frac{\pi}{4}\left(\frac{k}{2}\right)^4 + O(k^6) \right\} \\ -X_{01}^{1/2} &= -\frac{1}{3}\left(\frac{k}{2}\right)^2 - \frac{1}{5}\left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + iO(k^6) \\ -X_{11}^{1/2} &= 8 + \frac{8}{15}\left(\frac{k}{2}\right)^2 + \frac{1}{10}\left(\frac{k}{2}\right)^4 + O(k^6 \cdot \log k) + iO(k^6) \\ -X_{00}^{-1/2} &= 2 - \left(2 \log \frac{k}{2} + a_2\right)\left(\frac{k}{2}\right)^2 + \left\{ \frac{1^{**}}{24} - \frac{\pi^2}{2} + \frac{1}{2} \log \frac{k}{2} + \frac{a_3}{4} + \frac{1}{2} \left(2 \log \frac{k}{2} + a_2\right)^2 \right\} \left(\frac{k}{2}\right)^4 \end{aligned}$$

* See paper A, S. 201.

** $-X_{nv}^{-1/2}$ in the present paper corresponds to X_{nv}^* in the paper B, because $\sum_{v=0}^\infty G_{nv}^{-1/2} X_{vs}^{-1/2} = -\delta_{sn}$ is used instead of $\sum_{v=0}^\infty G_{nv}^{*-1/2} X_{vs}^* = \delta_{sn}$. $19/240 + \pi^2/2$ in the expression of X_{00}^* in B is incorrect, and to be replaced by $1/2 - \pi^2/2$.

$$\begin{aligned}
& +i\left\{-\pi\left(\frac{k}{2}\right)^2+\left(\frac{\pi}{4}+2\pi\log\frac{k}{2}+\pi a_2\right)\left(\frac{k}{2}\right)^4\right\}+O(k^6\cdot\log k)+iO(k^6) \\
-X_{01}^{-1/2} & =-\frac{1}{2}\left(\frac{k}{2}\right)^2+\left(-\frac{1}{16}+\frac{3}{4}\log\frac{k}{2}+\frac{a_2}{4}+\frac{a_4}{8}\right)\left(\frac{k}{2}\right)^4+O(k^6\cdot\log k)+i\left\{\frac{3\pi}{8}\left(\frac{k}{2}\right)^4+O(k^6)\right\}^* \\
-X_{11}^{-1/2} & =6+\frac{3}{4}\left(\frac{k}{2}\right)^2+\frac{27}{80}\left(\frac{k}{2}\right)^4+O(k^6\cdot\log k)+iO(k^6).
\end{aligned}$$

§ 4. Acoustic Field at Large Distance from the Source

It is shown in paper *A*, p. 202, that

$$\begin{aligned}
& \int_0^\infty \frac{J_m(\rho\xi)J_{m+2n+(3/2)}(\xi)}{\sqrt{\xi}} \exp(-\sqrt{\xi^2-k^2}z)d\xi \\
& = -\sqrt{\frac{2}{\pi}} \sum_{s=0}^\infty \frac{(-1)^s}{s! 2^{m+2n-(3/2)+2s} \Gamma(m+2n+s+\frac{5}{2})} \frac{1}{\rho^m} \left(\frac{1}{\rho} \frac{\partial}{\partial \rho}\right)^{n+1} \rho^{2(m+n+s)} \\
& \quad \cdot \frac{\partial}{\partial z} e^{i(\pi/2)(m+n+s+(1/2))} \left(\frac{k}{r}\right)^{m+n+s+(1/2)} K_{-(m+n+s+(1/2))}(ikr), \quad (23)
\end{aligned}$$

where $r=\sqrt{z^2+\rho^2}$.

For large distance r , using

$$H_\nu^{(1)}(z) \doteq \left(\frac{2}{\pi z}\right)^{1/2} \exp\left\{i\left(z-\frac{1}{2}\nu\pi-\frac{1}{4}\pi\right)\right\}$$

and

$$K_\nu(z) = \frac{\pi i}{2} I^{(1/2)\nu\pi i} H_\nu^{(1)}(iz) \doteq \sqrt{\frac{\pi}{2z}} e^{-z},$$

we obtain

$$K_{-(m+n+s+(1/2))}(ih\nu) \doteq \sqrt{\frac{\pi}{2ikr}} e^{-ikr}.$$

Then we have

$$\begin{aligned}
& \int_0^\infty \frac{J_m(\rho\xi)J_{m+2n+(3/2)}(\xi)}{\sqrt{\xi}} \exp(-\sqrt{\xi^2-k^2}z)d\xi \\
& \doteq (i)^{m+1} k \cos \theta \frac{e^{-ikr}}{r} \sum_{s=0}^\infty \frac{(-1)^s k^{m+2n+2s} (\sin \theta)^{m+2n+2s}}{s! 2^{m+2n+(3/2)+2s} \Gamma(m+2n+s+\frac{5}{2})} \\
& \quad \cdot \sum_{\nu=0}^{n+s} \frac{1}{\nu!} \frac{(n+s)!}{(n+s-\nu)!} \cdot \frac{(m+n+s)!}{(m+n+s-\nu)!} \left(-\frac{ik}{2}\right)^{-\nu} \frac{1}{r^\nu (\sin \theta)^{2\nu}}, \quad (24)
\end{aligned}$$

where $\rho/r=\sin \theta$, and θ denotes the angle between the normal to the ribbon plate and the vector from the middle line of plate to any point in the field.

For the point where r is large, taking only the term $\nu=0$ from the above formula, we have

$$\int_0^\infty \frac{J_m(\rho\xi)J_{m+2n+(3/2)}(\xi)}{\sqrt{\xi}} \exp(-\sqrt{\xi^2-k^2}z)d\xi \doteq (i)^{m+1} k \cos \theta \frac{e^{-ikr}}{r} \frac{J_{m+2n+(3/2)}(k \sin \theta)}{(k \sin \theta)^{3/2}}. \quad (25)$$

Using (25) and (3), we have

$$* \quad X_{01}^* = \frac{1}{2} \left(\frac{\gamma}{2}\right)^2 - \left(-\frac{1}{16} + \frac{3}{8} \log \frac{\gamma}{2} + \frac{a_2}{4} + \frac{a_4}{8}\right) \left(\frac{\gamma}{2}\right)^4 + O(\gamma^6 \cdot \log \gamma) - i \left\{ \frac{3\pi}{8} \left(\frac{\gamma}{2}\right)^4 + O(\gamma^6) \right\}$$

in *B* is incorrect, and to be replaced by the expression for $-X_{01}^{-1/2}$.

$$\Phi = \mp \sqrt{\frac{1}{\rho}} k \cos \theta \cdot \frac{e^{-ikr}}{r} i^{1/2} \sum_{n=0}^{\infty} \left\{ A_n^{1/2} i \frac{J_{(1/2)+2n+(3/2)}(k \sin \theta)}{(k \sin \theta)^{3/2}} + A_n^{-1/2} \frac{J_{-(1/2)+2n+(3/2)}(k \sin \theta)}{(k \sin \theta)^{3/2}} \right\}.$$

Then the velocity potential at large distance from the middle line of the ribbon plate is given by the equation

$$\Phi = \mp i^{1/2} k \cos \theta \cdot \sin^{1/2} \theta \frac{e^{-ikr}}{\sqrt{r}} \sum_{n=0}^{\infty} \left\{ i A_n^{1/2} \frac{J_{2n+2}(k \sin \theta)}{(k \sin \theta)^{3/2}} + A_n^{-1/2} \frac{J_{2n+1}(k \sin \theta)}{(k \sin \theta)^{3/2}} \right\}. \tag{26}$$

Obviously the sound wave becomes a cylindrical wave and its amplitude depends on the two-dimensional distribution of the source of vibration.

§ 5. Pressure on the Ribbon Plate

Denoting by σ the density of air, we can calculate the intensity of pressure $p e^{i\omega t}$ on the ribbon plate by the following formula:

$$p = i\omega\sigma(\Phi)_{z=0} = \mp i\omega\sigma\sqrt{\frac{1}{\rho}} \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \int_0^{\infty} \frac{J_{1/2}(\rho\xi)J_{(1/2)+2n+(3/2)}(\xi)}{\sqrt{\xi}} d\xi + A_n^{-1/2} \int_0^{\infty} \frac{J_{-1/2}(\rho\xi)J_{-(1/2)+2n+(3/2)}(\xi)}{\sqrt{\xi}} d\xi \right\}. \tag{27}$$

It is shown in reference (6), p. 199, that

$$\int_0^{\infty} \frac{J_{\mu}(\rho\xi)J_{\nu}(\xi)}{\xi^{\lambda}} d\xi = \rho^{\mu} \frac{\Gamma\{(\mu+\nu+1-\lambda)/2\}}{2^{\lambda}\Gamma(\mu+1)\Gamma\{(\lambda+\nu+1-\mu)/2\}} F\left\{\frac{\mu+\nu+1-\lambda}{2}, \frac{\mu+1-\lambda-\nu}{2}, \mu+1, \rho^2\right\}.$$

$\left(x = \rho^2 \leq 1, \quad \rho = \frac{y}{a}\right).$

Setting

$$S_n^m(y, 0) = \sqrt{\frac{y}{a}} \int_0^{\infty} \frac{J_m(y/a \cdot \xi)J_{m+2n+(3/2)}(\xi)}{\sqrt{\xi}} d\xi,$$

we have

$$\begin{aligned} S_n^{-1/2}(y, 0) &= \sqrt{\frac{2}{\pi}} \frac{1}{(2n+1)} (1-\rho^2) F\left(-n, n+1, \frac{1}{2}, \rho^2\right) \\ &= \frac{\sqrt{2}}{\Gamma(n+\frac{3}{2})} \frac{1}{2n+1} x^{1/2} \frac{d^n}{dx^n} \{x^{n-(1/2)}(1-x)^{n+(1/2)}\} = \frac{1}{2n+1} (1-x)^{1/2} v_n^{-1/2}(x), \\ S_n^{1/2}(y, 0) &= \sqrt{\frac{2}{\pi}} \rho (1-\rho^2)^{1/2} F\left(-n, n+2, \frac{3}{2}, \rho^2\right) \\ &= \frac{1}{\sqrt{2}} \frac{1}{\Gamma(n+\frac{3}{2})} \frac{d^n}{dx^n} \{x^{n+(1/2)}(1-x)^{n+(1/2)}\} = \frac{1}{2(n+1)} \sqrt{x} (1-x)^{1/2} v_n^{1/2}(x). \end{aligned}$$

Therefore by the equation (27) we obtain, as the pressure on the ribbon plate,

$$\begin{aligned} p &= \mp i\omega\sigma \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \frac{1}{2(n+1)} \sqrt{x} (1-x)^{1/2} v_n^{1/2}(x) + A_n^{-1/2} \frac{1}{2n+1} (1-x)^{1/2} v_n^{-1/2}(x) \right\} \\ &= \mp i\omega\sigma \sum_{n=0}^{\infty} \left\{ A_n^{1/2} \frac{1}{2(n+1)} \rho (1-\rho^2)^{1/2} v_n^{1/2}(\rho^2) + A_n^{-1/2} \frac{1}{2n+1} (1-\rho^2)^{1/2} v_n^{-1/2}(\rho^2) \right\}, \end{aligned} \tag{28}$$

or we can express b in another form,

$$\begin{aligned} p &= \mp i\omega\sigma \sum_{n=0}^{\infty} \left[A_n^{-1/2} \frac{\sqrt{2}}{\Gamma(n+\frac{3}{2})} \frac{1}{2n+1} x^{1/2} \frac{d^n}{dx^n} \{x^{n-(1/2)}(1-x)^{n+(1/2)}\} \right. \\ &\quad \left. + A_n^{1/2} \frac{1}{\sqrt{2}} \frac{1}{\Gamma(n+\frac{3}{2})} \frac{d^n}{dx^n} \{x^{n+(1/2)}(1-x)^{n+(1/2)}\} \right]. \end{aligned} \tag{29}$$

The total pressure are unit length, P , on the ribbon plate is expressed as follows,

$$P = \int_{-a}^a (p_{z=+0} - p_{z=-0}) dy = a \int_{-1}^1 (p_{z=+0} - p_{z=-0}) d\rho. \quad (30)$$

Owing to the formula (29), we have

$$P = -2i\omega\sigma a \sum_{n=0}^{\infty} \left[A_n^{-1/2} \frac{\sqrt{2}}{\Gamma(n+\frac{1}{2})} \frac{1}{2n+1} \int_{-1}^1 x^{1/2} \frac{d^n}{dx^n} \{x^{n-(1/2)}(1-x)^{n+(1/2)}\} d\rho \right. \\ \left. + A_n^{1/2} \frac{1}{\sqrt{2}} \frac{1}{\Gamma(n+\frac{3}{2})} \int_{-1}^1 \frac{d^n}{dx^n} \{x^{n+(1/2)}(1-x)^{n+(1/2)}\} d\rho \right].$$

In the above formula the first series corresponds to an integration of even terms, and the second series corresponds to odd terms, so that the value of second vanishes; accordingly we obtain the following expression

$$P = -2i\omega\sigma a \sum_{n=0}^{\infty} A_n^{-1/2} \frac{\sqrt{2}}{\Gamma(n+\frac{1}{2})} \frac{1}{2n+1} \int_{-1}^1 x^{1/2} \frac{d^n}{dx^n} \{x^{n-(1/2)}(1-x)^{n+(1/2)}\} d\rho.$$

The integral for $n=0$ has the value $\pi/2$ and has the value zero for $n=1, 2, 3, \dots$, so that we have

$$P = -i\omega\sigma a \sqrt{\frac{\pi}{2}} A_0^{-1/2}. \quad (31)$$

§ 6. Power of Radiation

The total power radiated per unit length is given by the real part of the quantity,

$$W = 2a \int_{-1}^1 \frac{\tilde{p}\tilde{v}}{2} d\rho. \quad (32)$$

Here $\sim$ means conjugate complex.

The velocity of the air on the ribbon plate, v is given by the following formula

$$v = \frac{1}{a} \{f_e(\rho) + f_v(\rho)\} = \frac{1}{a} \left\{ \sum_{m=0}^{\infty} a_m^{-1/2} v_m^{-1/2}(x) + \sqrt{x} \sum_{m=0}^{\infty} a_m^{1/2} v_m^{1/2}(x) \right\},$$

but at substitution of the expressions of p and $\tilde{v}$ in (32), we may only use the even term of $p \cdot \tilde{v}$. The even term takes the form,

$$\left(\frac{p \cdot \tilde{v}}{2} \right)_{\text{even}} = -\frac{1}{2a} i\omega\sigma \left\{ \left(\sum_{m=0}^{\infty} \tilde{a}_m^{-1/2} v_m^{-1/2}(x) \right) \left(\sum_{n=0}^{\infty} A_n^{-1/2} \frac{1}{2n+1} (1-x)^{1/2} v_n^{-1/2}(x) \right) \right. \\ \left. + \left(\sqrt{x} \sum_{m=0}^{\infty} \tilde{a}_m^{1/2} v_m^{1/2}(x) \right) \left(\sum_{n=0}^{\infty} A_n^{1/2} \frac{1}{2(n+1)} \sqrt{x} (1-x)^{1/2} v_n^{1/2}(x) \right) \right\}.$$

Using (see Appendix)

$$2 \int_0^1 (1-x)^{1/2} v_m^{-1/2}(x) v_n^{-1/2}(x) dx = \delta_{mn} \\ 2 \int_0^1 x (1-x)^{1/2} v_m^{1/2}(x) v_n^{1/2}(x) dx = \delta_{mn},$$

we have

$$W = 4a \int_0^1 \left(\frac{pv}{2} \right)_{\text{even}} d\rho = -i\omega\sigma \sum_{m=0}^{\infty} \left\{ \tilde{a}_m^{-1/2} A_m^{-1/2} \frac{1}{2m+1} + \tilde{a}_m^{1/2} A_m^{1/2} \frac{1}{2(m+1)} \right\}. \quad (33)$$

§ 7. Conclusion

The unknown coefficients $A_n^{1/2}$ and $A_n^{-1/2}$ in the formula (3) giving the velocity potential are determined from the equation (16) in terms of the coefficients $a_n^{1/2}$ and $a_n^{-1/2}$ in the expansion of the velocity distribution (4) in a series of hypergeometric polynomials. The solution of equation (16) is obtained from (18) using the tables for $X_{nv}^{1/2}$ and $X_{nv}^{-1/2}$ which is a solution of equation (17). Therefore, if we determine the coefficients $a_n^{1/2}$ and $a_n^{-1/2}$ by the formula (8) from the velocity distribution on the ribbon plate, we obtain a solution of the problem.

But these tables are given in the present paper only for small values of k . We intend to publish the tables of X_{nv}^m in the next report II.

At large distance, the velocity potential is given by the formula (26) and it expresses a cylindrical wave. The deviation of the amplitude from the $\cos \theta$ -distribution depends upon the wave length and the distribution of the vibrating sources. For the direction $\theta=0$, the odd part of the velocity distribution function does not contribute to the velocity potential at large distance.

In the end we indicated a method of calculation for the power of radiation from the vibrating plate.

Appendix

We have (see reference (6), p. 201)

$$\begin{aligned} v_n^m(x) &= \frac{\sqrt{2} \Gamma(m+n+\frac{3}{2})}{n! \Gamma(m+n+1)} x^{-m} (1-x)^{-1/2} \frac{d^n}{dx^n} \{x^{m+n}(1-x)^{n+(1/2)}\} \\ &\cdot \int_0^1 x^m (1-x)^{1/2} v_n^m(x) v_{n'}^m(x) dx = 0 \quad n' \neq n \\ &= \frac{2\Gamma(n+\frac{3}{2})\Gamma(m+n+\frac{3}{2})}{(m+2n+\frac{3}{2})n! \Gamma(m+n+1)} \quad n' = n \end{aligned}$$

Using above formulas, and taking $m=(-1)/2$, $+1/2$ and $x=\rho^2$,

$$\begin{aligned} 2 \int_0^1 (1-x)^{1/2} v_n^{-1/2}(x) v_n^{-1/2}(x) d\rho &= \int_0^1 x^{-1/2} (1-x)^{1/2} v_n^{-1/2}(x) v_n^{-1/2}(x) dx \\ &= \frac{2\Gamma(n+\frac{3}{2})\Gamma(-\frac{1}{2}+n+\frac{3}{2})}{(-\frac{1}{2}+2n+\frac{3}{2})n! \Gamma(-\frac{1}{2}+n+1)} = 1, \\ 2 \int_0^1 x(1-x)^{1/2} v_n^{1/2}(x) v_n^{1/2}(x) d\rho &= \int_0^1 x^{1/2} (1-x)^{1/2} v_n^{1/2}(x) v_n^{1/2}(x) dx \\ &= \frac{2\Gamma(n+\frac{3}{2})\Gamma(\frac{1}{2}+n+\frac{3}{2})}{(\frac{1}{2}+2n+\frac{3}{2}) \cdot n! \cdot \Gamma(\frac{1}{2}+n+1)} = 1. \end{aligned}$$

A New Approach to the Theory of Slender Body in Compressible Flow

By Haruo MORIGUCHI

*Department of Physics, Faculty of Liberal Arts,
Shizuoka University, Shizuoka*

(Received July 26, 1958)

It is shown that the equation of perturbation given to a known two-dimensional or axisymmetric flow of compressible fluid can be written in a simple form by choosing appropriate coordinates.

From an approximate solution of this equation in the case of a slender body, we can deduce a velocity transformation formula

$$\int_U^q \frac{\sqrt{1-q^2/c^2}}{q} dq = \log \left(\frac{q}{U} \right)_i,$$

where q , c and U are the velocity of fluid at an arbitrary point on the surface of the body, the local velocity of sound and the velocity of free stream (the critical speed of sound being taken as the unit of velocity), and $(q/U)_i$ is the velocity of incompressible flow at the same point taking the velocity of free stream as unit.

Though this result has been given earlier by Imai in two-dimensional case and by Kusakawa in axisymmetric case, our deduction gives it as a first approximate solution which could be refined by a procedure of successive approximations. It is also expected that the perturbation equation will play some important role in mathematical discussion on mixed flow problems.

§ 1. Introduction

For treating subsonic flow of a compressible fluid past a slender body, methods of successive approximations, starting from the Prandtl-Glauert rule as a first approximation, are often used, and especially in the two-dimensional case some examples, e.g. elliptic cylinders¹⁾ and circular arc aerofoils²⁾, have been worked out to higher-order approximations. These methods, however, are believed to be unsuitable for treating such flows as involving nearly sonic speeds.

Imai^{3),4),5)} offered a new procedure to treat the two-dimensional flow and deduced a transformation formula which gives the velocity of compressible flow directly from the velocity of the corresponding incompressible flow, and Kusakawa^{6),7)} extended the formula to the case of axisymmetric flow. Though these methods seem to represent the flow pattern more precisely than the usual slender body theory, the prescribed boundary conditions cannot always be satisfied exactly, and it is not clear how to proceed to higher-order ap-

proximations.

In this paper, we first give a simple representation of the perturbations for a flow of compressible fluid and then, in the case of a slender body, we find approximate solutions which satisfy the exact boundary conditions and show that our result leads immediately to Imai's formula.

Our perturbation equation is essentially the same as the usual one which, for example, has been used by Bers⁸⁾ in the discussion of mixed flow problems, but is expressed in a more simplified form by a suitable choice of independent variables. Therefore we may expect that our equation can play some important role in the mathematical discussion on transonic flow.

The higher-order approximations for our equation may be found by the usual method of iteration. But it seems difficult to find an analytical formula which covers a wide range of Mach number.

We shall treat the two-dimensional case in §§2~5 and axisymmetric case in §6, and show the slide rule technique for the calculation of velocity in §7.

§ 2. Fundamental Equations in Two-dimensional Case

The two-dimensional irrotational flow of a compressible fluid is governed by the equations:

$$u = \frac{\partial \Phi}{\partial x} = \frac{1}{P} \frac{\partial \Psi}{\partial y}, \tag{2.1}$$

$$v = \frac{\partial \Phi}{\partial y} = - \frac{1}{P} \frac{\partial \Psi}{\partial x}, \tag{2.2}$$

$$P = \left(\frac{\gamma+1}{2} - \frac{\gamma-1}{2} Q^2 \right)^{1/(\gamma-1)}, \tag{2.3}$$

$$Q^2 = u^2 + v^2, \tag{2.4}$$

where (u, v) are the component velocities in the x - and y -directions, Q is the magnitude of velocity, P is the density, Φ is the velocity potential, Ψ is the stream function, and γ is the ratio of specific heats. In these as well as in the following expressions we take as units the values at the critical state where the local velocity of sound C is equal to flow velocity Q . For the local velocity of sound we have

$$C^2 = \frac{\gamma+1}{2} - \frac{\gamma-1}{2} Q^2. \tag{2.5}$$

Let us suppose that the solution for a uni-

form flow of free stream velocity U past a given obstacle is already known:

$$u_0 = \frac{\partial \varphi}{\partial x} = \frac{1}{\rho} \frac{\partial \phi}{\partial y}, \tag{2.6}$$

$$v_0 = \frac{\partial \varphi}{\partial y} = - \frac{1}{\rho} \frac{\partial \phi}{\partial x}, \tag{2.7}$$

$$\rho = \left(\frac{\gamma+1}{2} - \frac{\gamma-1}{2} q^2 \right)^{1/(\gamma-1)}, \tag{2.8}$$

$$q^2 = u_0^2 + v_0^2, \tag{2.9}$$

and choose φ and ϕ as independent variables. Then the fundamental equations can be written as

$$\frac{\partial \Phi}{\partial \varphi} = \frac{\rho}{P} \frac{\partial \Psi}{\partial \phi}, \tag{2.10}$$

$$\frac{\partial \Phi}{\partial \phi} = - \frac{1}{\rho P} \frac{\partial \Psi}{\partial \varphi}. \tag{2.11}$$

The relations between (x, y) and (φ, ϕ) are given by (2.6), (2.7) and the inverse relations:

$$\frac{\partial x}{\partial \varphi} = \frac{u_0}{q^2}, \tag{2.12}$$

$$\frac{\partial y}{\partial \varphi} = \frac{v_0}{q^2}, \tag{2.13}$$

$$\frac{\partial x}{\partial \phi} = - \frac{v_0}{\rho q^2}, \tag{2.14}$$

$$\frac{\partial y}{\partial \phi} = \frac{u_0}{\rho q^2}. \tag{2.15}$$

When we consider the flow of a different free stream velocity $U + \Delta U$ about the same obstacle, the boundary conditions for (2.10) and (2.11) are given by

$$\Psi = \text{const. on the surface of the obstacle}, \tag{2.16}$$

and

$$\left. \begin{aligned} \frac{\partial \Psi}{\partial \phi} &\rightarrow \frac{P_\infty}{\rho_\infty} \frac{U + \Delta U}{U}, \end{aligned} \right\} \tag{2.17}$$

$$\left. \begin{aligned} \frac{\partial \Phi}{\partial \varphi} &\rightarrow \frac{U + \Delta U}{U}, \end{aligned} \right\} \tag{2.18}$$

$$\left. \begin{aligned} \frac{\partial \Psi}{\partial \varphi} &\rightarrow 0, \end{aligned} \right\} \text{at infinity}, \tag{2.19}$$

$$\left. \begin{aligned} \frac{\partial \Phi}{\partial \phi} &\rightarrow 0, \end{aligned} \right\} \tag{2.20}$$

where P_∞ and ρ_∞ are the free stream density of the unknown and known flow respectively. We can put

$$\Psi = \phi = 0 \tag{2.21}$$

on the surface of obstacle.

§ 3. Perturbation Equations

Now let us consider the case in which the difference ΔU is so small that Φ and Ψ are very close to φ and ψ respectively. Then we can put

$$\Phi = \varphi + \varphi', \quad (3.1)$$

$$\Psi = \psi + \psi', \quad (3.2)$$

$$P = \rho + \rho', \quad (3.3)$$

$$Q = q + q', \quad (3.4)$$

and neglect the second and higher order terms in primed quantities. Thus we have, from (1.3),

$$\rho' = -\frac{q\rho}{c^2} q' \quad (3.5)$$

and, from (2.1), (2.2) and (2.4),

$$q' = q \frac{\partial \varphi'}{\partial \varphi}, \quad (3.6)$$

or, making use of (2.10),

$$q' = \frac{q}{\mu^2} \frac{\partial \psi'}{\partial \psi}, \quad (3.7)$$

where

$$\mu^2 = 1 - q^2/c^2, \quad (3.8)$$

and c is the local velocity of sound corresponding to q . Substituting these expressions in (2.10) and (2.11) we have for φ' and ψ'

$$\mu^2 \frac{\partial \varphi'}{\partial \varphi} = \frac{\partial \psi'}{\partial \psi}, \quad (3.9)$$

$$\rho^2 \frac{\partial \varphi'}{\partial \psi} = -\frac{\partial \psi'}{\partial \varphi}, \quad (3.10)$$

or eliminating ψ' or φ'

$$\frac{\partial}{\partial \varphi} \left(\mu^2 \frac{\partial \varphi'}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\rho^2 \frac{\partial \varphi'}{\partial \psi} \right) = 0, \quad (3.11)$$

$$\frac{\partial}{\partial \varphi} \left(\frac{1}{\rho^2} \frac{\partial \psi'}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\frac{1}{\mu^2} \frac{\partial \psi'}{\partial \psi} \right) = 0. \quad (3.12)$$

These are the basic equations for our discussions.

As is seen from our deduction, when the boundary conditions for φ' and ψ' are given by

$$\left. \begin{aligned} \frac{\partial \varphi'}{\partial \psi} &= 0, \\ \psi' &= 0, \end{aligned} \right\} \text{ on the surface} \quad (3.13)$$

$$(3.14)$$

and

$$\left. \begin{aligned} \frac{\partial \varphi'}{\partial \varphi} &\rightarrow \frac{1}{U}, \\ \frac{\partial \varphi'}{\partial \psi} &\rightarrow 0, \end{aligned} \right\} \text{ at infinity,} \quad (3.15)$$

$$(3.16)$$

$$\left. \begin{aligned} \frac{\partial \psi'}{\partial \psi} &\rightarrow \frac{\mu_\infty^2}{U}, \\ \frac{\partial \psi'}{\partial \varphi} &\rightarrow 0, \end{aligned} \right\} \quad (3.17)$$

$$(3.18)$$

where the suffix ∞ means the value at infinity, then φ' and ψ' denote respectively

$$\varphi' = \frac{\partial \varphi(x, y, U)}{\partial U}, \quad (3.19)$$

and

$$\psi' = \frac{\partial \psi(x, y, U)}{\partial U}, \quad (3.20)$$

where $\varphi(x, y, U)$ and $\psi(x, y, U)$ are the velocity potential and stream function for the flow about the given obstacle with the free stream velocity U . This fact will be used in the following sections.

If we take x and y as independent variables in (3.11), then we have

$$(c^2 - u_0^2) \frac{\partial^2 \varphi'}{\partial x^2} - 2u_0 v_0 \frac{\partial^2 \varphi'}{\partial x \partial y} + (c^2 - v_0^2) \frac{\partial^2 \varphi'}{\partial y^2} + A \frac{\partial \varphi'}{\partial x} + B \frac{\partial \varphi'}{\partial y} = 0, \quad (3.21)$$

where A and B are certain functions of x and y . This is the form which has been employed, for example, by Bers⁹⁾.

§ 4. Simple Approximate Solutions for Thin Aerofoil

In the case of a thin aerofoil where the disturbance due to the presence of the aerofoil is small, we can deduce simple approximate solutions of our equation (3.11) or (3.12).

For this purpose, let us put

$$\psi' = \mu \psi^* \quad (4.1)$$

in (3.12). Then we have

$$\frac{\partial}{\partial \varphi} \left(\frac{\mu^2}{\rho^2} \frac{\partial \psi^*}{\partial \varphi} \right) + \frac{\partial^2 \psi^*}{\partial \psi^2} + J \psi^* = 0, \quad (4.2)$$

where

$$J = \mu \frac{\partial}{\partial \varphi} \left(\frac{1}{\rho^2} \frac{\partial \mu}{\partial \varphi} \right) + \mu \frac{\partial}{\partial \psi} \left(\frac{1}{\mu^2} \frac{\partial \mu}{\partial \psi} \right). \quad (4.3)$$

The boundary conditions for ψ^* are the same as those for ψ' given by (3.14) and (3.18).

Since μ and ρ are functions of q , (4.3) can be written as

$$J = \mu \left\{ \frac{\partial}{\partial \varphi} \left(\frac{\mu'}{\rho^2} \frac{\partial q}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\frac{\mu'}{\mu^2} \frac{\partial q}{\partial \psi} \right) \right\}, \quad (4.4)$$

where

$$\mu' = d\mu/dq. \quad (4.5)$$

Now we have, by means of (2.12)~(2.15), the relations

$$\frac{\partial q}{\partial \varphi} = -\frac{\rho q}{\mu^2} \frac{\partial \theta}{\partial \psi}, \quad (4.6)$$

$$\frac{\partial q}{\partial \psi} = \frac{q}{\rho} \frac{\partial \theta}{\partial \psi}, \quad (4.7)$$

where

$$\theta = \tan^{-1}(v_0/u_0). \quad (4.8)$$

Eliminating θ from (4.6) and (4.7), we have

$$\frac{\partial}{\partial \varphi} \left(\frac{\mu^2}{\rho q} \frac{\partial q}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\frac{\rho}{q} \frac{\partial q}{\partial \psi} \right) = 0. \quad (4.9)$$

Substituting (4.9) into (4.4) we have

$$J = \left\{ \frac{\mu^2}{\rho^2} \left(\frac{\partial q}{\partial \varphi} \right)^2 + \left(\frac{\partial q}{\partial \psi} \right)^2 \right\} j(q), \quad (4.10)$$

where

$$j(q) = \left(\frac{\mu}{\rho^2} \frac{d\rho^2}{dq} - \frac{\mu^3}{q} \right) \frac{d}{dq} \left(\frac{1}{\mu} \right) - \mu \frac{d^2}{dq^2} \left(\frac{1}{\mu} \right). \quad (4.11)$$

If the deviation from the uniform flow is small, the bracketed factor in (4.10) can be regarded as small quantity of the second order, as is obvious when we write

$$q = U + \varepsilon q_1, \quad (4.12)$$

where ε is a small parameter. Therefore in this case we can neglect J in (4.2) except the case in which there appears sonic speed which makes $j(q)$ singular, and we have an approximate solution

$$\psi^* = \text{const. } \psi = c_1 \psi, \quad (4.13)$$

which satisfies the boundary conditions (3.14) and (3.18).

From this solution, we have, by means of (3.7) and (2.21),

$$q_s' = c_1 \frac{q_s}{\mu_s} \quad (4.14)$$

for the perturbation surface velocity, where the suffix s denotes the value on the surface of the obstacle.

According to the remark given in § 3, when we put

$$c_1 = \frac{\mu_\infty}{U}, \quad (4.15)$$

q_s' can be regarded as the approximate value of the partial derivative of q_s with respect to U :

$$\frac{\partial q_s}{\partial U} = \frac{\mu_\infty}{U} \frac{q_s}{\mu_s}, \quad (4.16)$$

or

$$\frac{\partial q_s}{\partial U} = \frac{\sqrt{1-U^2/c_\infty^2}}{U} \frac{q_s}{\sqrt{1-q_s^2/c_s^2}}. \quad (4.17)$$

On integration we have

$$\int_{q_s}^1 \frac{\sqrt{1-q_s^2/c_s^2}}{q_s} dq_s = \int_U^1 \frac{\sqrt{1-U^2/c_\infty^2}}{U} dU + \text{const.}, \quad (4.18)$$

where const. means a function of coordinates only.

If U tends to zero, then q_s must also tend to zero; therefore for small values of U we have

$$-\log q_s = -\log U + \text{const.} \quad (4.19)$$

This means that the constant should be equal to

$$\lim_{U \rightarrow 0} \left(-\log \frac{q_s}{U} \right) = -\log \left(\frac{q_s}{U} \right)_i, \quad (4.20)$$

where the suffix i denotes the incompressible flow. Thus we have finally

$$\begin{aligned} & \int_{q_s}^1 \frac{\sqrt{1-q_s^2/c_s^2}}{q_s} dq_s \\ &= \int_U^1 \frac{\sqrt{1-U^2/c_\infty^2}}{U} dU - \log \left(\frac{q_s}{U} \right)_i, \end{aligned} \quad (4.21)$$

which is the transformation formula given by Imai^{3),4),5)}.

It is to be noticed that in our deduction the boundary conditions are satisfied completely in contrast to Imai's deduction.

Further, since the functional relation between c_s and q_s is the same as that between c_∞ and U , we can rewrite (4.21) as

$$\int_U^{q_s} \frac{\sqrt{1-q^2/c^2}}{q} dq = \log \left(\frac{q_s}{U} \right)_i. \quad (4.22)$$

Similar procedure gives another approximate solution. Let us consider Eq. (3.11), and put

$$\varphi' = \frac{\varphi^*}{\mu}. \quad (4.23)$$

Then we have

$$\frac{\partial^2 \varphi^*}{\partial \varphi^2} + \frac{\partial}{\partial \psi} \left(\frac{\rho^2}{\mu^2} \frac{\partial \varphi^*}{\partial \psi} \right) + K \varphi^* = 0, \quad (4.24)$$

where K is a small factor of the second order as can be seen from consideration similar to that given in the preceding case. Neglecting $K \varphi^*$ we have an approximate solution:

$$\varphi^* = C_2 \varphi \quad (4.25)$$

which satisfies the boundary conditions at infinity.

In this case, however, the boundary condition on the surface of the obstacle is not satisfied. The velocity potential corresponding to (4.25) may be regarded as one which represents a flow with a slightly different boundary. But when we neglect the term which contains $(\partial/\partial\psi)(1/\mu)$, (4.25) satisfies the boundary conditions and give the perturbation surface velocity in the form;

$$q_s' = C_2 \frac{q_s}{\mu_s} + C_2 \varphi_s \frac{\partial}{\partial s} \left(\frac{1}{\mu_s} \right), \quad (4.26)$$

where s means length along the surface. The first term is in accord with (4.14).

The difference between (4.14) and (4.26) can be interpreted to be due to the fact that in the velocity potential procedure the boundary conditions are only approximately satisfied while in the stream function procedure the conditions are exactly fulfilled, so that (4.14) should be regarded as superior to (4.26).

Finally a comment is added here. When we put

$$C_2 = \frac{\mu_\infty}{U}, \quad (4.27)$$

we have an approximate relation

$$\frac{\partial \varphi_s}{\partial U} = \frac{\mu(U)}{\mu(q_s)} \frac{\varphi_s}{U}, \quad (4.28)$$

where

$$\mu(q) = 1 - q^2/c^2, \quad (4.29)$$

as is seen from the remark in § 3. Since

$$q_s = \frac{\partial \varphi_s}{\partial s}, \quad (4.30)$$

we can regard (4.28) as a partial differential equation for φ_s with independent variables s and U .

§ 5. Complex Formulation of the Preceding Procedure and the Possibility of Higher-Order Approximations

We can write the procedure in a more compact form as follows.

Let us put

$$\varphi = \xi, \quad (5.1)$$

$$\psi = \frac{\rho_\infty}{\mu_\infty} \eta, \quad (5.2)$$

and use φ^* and ψ^* given by (4.1) and (4.23). Then (3.9) and (3.10) become

$$\frac{\partial \varphi^*}{\partial \eta} + \frac{\partial \psi^*}{\partial \xi} = \varphi^* \frac{\partial \alpha}{\partial \eta} - (1 + \delta) \psi^* \frac{\partial \alpha}{\partial \xi} - \delta \frac{\partial \psi^*}{\partial \xi}, \quad (5.3)$$

$$\frac{\partial \varphi^*}{\partial \xi} - \frac{\partial \psi^*}{\partial \eta} = \varphi^* \frac{\partial \alpha}{\partial \xi} + \psi^* \frac{\partial \alpha}{\partial \eta}, \quad (5.4)$$

where

$$\alpha = \log \mu, \quad (5.5)$$

$$\delta = \frac{\mu^2 \rho_\infty^2}{\rho^2 \mu_\infty^2} - 1. \quad (5.6)$$

It is to be noted that for Kármán-Tsien's gas

$$\delta = 0. \quad (5.7)$$

Further let us put

$$\varphi^* + i\psi^* = F, \quad (5.8)$$

$$\varphi^* - i\psi^* = \bar{F}, \quad (5.9)$$

$$\xi + i\eta = \zeta, \quad (5.10)$$

$$\xi - i\eta = \bar{\zeta}, \quad (5.11)$$

then (5.3) and (5.4) can be combined into

$$2 \frac{\partial F}{\partial \bar{\zeta}} = 2 \bar{F} \frac{\partial \alpha}{\partial \bar{\zeta}} - \frac{\delta}{2} (F - \bar{F}) \left(\frac{\partial \alpha}{\partial \zeta} + \frac{\partial \alpha}{\partial \bar{\zeta}} \right) - \frac{\delta}{2} \left(\frac{\partial F}{\partial \zeta} - \frac{\partial \bar{F}}{\partial \zeta} + \frac{\partial F}{\partial \bar{\zeta}} - \frac{\partial \bar{F}}{\partial \bar{\zeta}} \right), \quad (5.12)$$

and the approximate solutions given in the preceding section are the imaginary and real parts of

$$F_0 = C_0 \zeta, \quad (5.13)$$

which is a solution of approximate equation obtainable when we neglect the right-hand side of (5.12).

At first sight F_0 would seem to be an approximation neglecting the small quantities of the first order, but as we have shown in the preceding section, (5.13) gives a higher approximate solution.

Now we can see the possibility of successive approximations starting from (5.13), although the procedure of calculation is a problem left to future.

§ 6. The Case of Axisymmetric Flow

The fundamental equations for axisymmetric flow are

$$u = \frac{\partial \Phi}{\partial x} = \frac{1}{Py} \frac{\partial \Psi}{\partial y}, \quad (6.1)$$

$$v = \frac{\partial \Phi}{\partial y} = -\frac{1}{Py} \frac{\partial \Psi}{\partial x}, \quad (6.2)$$

where x and y are the coordinates parallel and perpendicular to the axis of symmetry, u and v are the component velocities in the x - and y -directions, Φ is the velocity potential, Ψ is Stokes' stream function and other quantities are the same as those in the two-dimensional case.

If we know a flow represented by φ and ψ , we can write the fundamental equations as

$$\frac{\partial \Phi}{\partial \varphi} = \frac{\rho}{P} \frac{\partial \Psi}{\partial \psi}, \quad (6.3)$$

$$\frac{\partial \Phi}{\partial \psi} = -\frac{1}{\rho P} \frac{1}{y^2} \frac{\partial \Psi}{\partial \varphi}, \quad (6.4)$$

and the perturbation equations for

$$\varphi' = \Phi - \varphi, \quad (6.5)$$

$$\psi' = \Psi - \psi \quad (6.6)$$

can be deduced in a similar way to that in § 4:

$$\frac{\partial}{\partial \varphi} \left(\mu^2 \frac{\partial \varphi'}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\rho^2 y^2 \frac{\partial \varphi'}{\partial \psi} \right) = 0, \quad (6.7)$$

$$\frac{\partial}{\partial \varphi} \left(\frac{1}{\rho^2 y^2} \frac{\partial \psi'}{\partial \varphi} \right) + \frac{\partial}{\partial \psi} \left(\frac{1}{\mu^2} \frac{\partial \psi'}{\partial \psi} \right) = 0, \quad (6.8)$$

which correspond respectively (3.11) and (3.12).

These equations are of the same forms as (3.11) and (3.12) except that (6.7) and (6.8) have $\rho^2 y^2$ in place of ρ^2 in (3.11) and (3.12).

Accordingly we get the same approximate solutions and velocity transformation formula as in § 4.

The velocity transformation formula for the

case of axisymmetric flow has been derived by Kusakawa^{6),7)} in a different way. As he has also pointed out, in this case the neglected term corresponding to J in (4.2) or K in (4.24) is a small quantity of the first order, whereas it was of the second order in the two-dimensional case.

§ 7. Slide Rule for the Calculation of Velocity

As is seen from the form of (4.22), our formula permits slide rule calculations, when we know the velocity distribution at a certain Mach number, for example, at zero Mach number. In this section such a slide rule is considered.

Fig. 1 shows the slide rule for the flow of adiabatic gas with $\gamma=1.4$. On the A-rule the value of q is marked at the point where the distance from the mark q_0 is

Fig. 1. Slide rule for calculation of velocity.

$$\int_{q_0}^q \frac{\sqrt{1-q^2/c^2}}{q} dq,$$

where q_0 is a proper standard value. On the B-rule the value of $(q/U)_i$ is marked at the point where the distance from the mark 1 is $\log (q/U)_i$.

The graduation C denotes the Mach number corresponding to the free stream velocity graduated on the A-rule.

Now let us find the velocity at a point on the aerofoil, where the velocity for incompressible flow is $(q/U)_i$. We should make the mark 1 on the B-rule in line with the mark U or mark M on the A or C-graduation, where U or M means the velocity of free stream or Mach number of the flow required.

Then the mark on A-rule, which is in line with $(q/U)_i$ on B-rule is the velocity required. Of course the critical speed is taken as the unit of velocity.

Fig. 1 shows the corresponding relations between the incompressible flow and the flow

of Mach number 0.5; if, for example, $(q/U)_i$ is 1.1, then at such a point q is 0.598 when the Mach number is 0.5.

Acknowledgements

The author wishes to express his sincere thanks to Professor I. Imai of the University of Tokyo who kindly read the manuscript and gave him much valuable advice after continued encouragement, and to the members of Professor Imai's seminar for their useful discussions.

The author is indebted to the Ministry of Education for a grant.

Attenuation of Ultrasonic Waves in Suspensions of Viscoelastic Spheres

By Yasaku WADA

*Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Bunkyo-ku, Tokyo*

(Received July 7, 1958)

The attenuation of ultrasonic waves for suspensions of polymethyl methacrylate particles (mean radius $a \approx \text{ca. } 40\mu$) in ethyl alcohol, carbon tetrachloride and their mixtures are measured in the range of frequency 1–6 Mc/s. For $ka > 0.5$ ($k = 2\pi/\text{wave length}$) the scattering and reflection losses are found to be predominant origins of the attenuation. But when ka approaches unity, the observed attenuation lies markedly below the prediction from Rayleigh's formula which is established under the condition of $ka \ll 1$. For $ka < 0.5$, the viscous loss predicted by Lamb and Urick and the loss due to the internal viscosity of suspended particles become appreciable. A simple theory for the latter loss is developed under some assumptions. The sum of the theoretical values of these three kinds of losses is in satisfactory agreement with the experimental one. In the frequency range where the internal loss predominates, the method employed in this research can be used to measure the volume viscosity of a solid material.

§ 1. Introduction

The attenuation of sound in suspensions or hydrosols is of great importance in underwater sound transmission, in the study of colloidal systems and in many other applications. While the attenuation properties of homogeneous liquids and solids have been widely studied and are now well known, the amount of study in suspensions has been rather limited. The first calculation of the attenuation of sound due to the scattering by a single sphere suspended in a non-viscous liquid was made by Rayleigh.¹⁾ Lamb²⁾ calculated the velocity potential of waves scattered from a mobile sphere in a viscous liquid. Urick³⁾ cast Lamb's theory in a more convenient form and obtained the attenuation due to the relative motion of a sphere in a viscous liquid.

Since most of the previous experiments^{3, 4, 5)}

in this relation have been made for aqueous suspensions of natural powders, for example, kaolin, quartz sand, lycopodium etc. which are not perfectly spherical in shape and mechanical properties of which are not well determined, the results could not be quantitatively compared with theory. Busby and Richardson⁶⁾ recently investigated the attenuation of sound in aqueous suspensions of glass spheres and the result was accurately explained in terms of scattering and viscous loss. In this case, however, since the density and elastic modulus are much higher in glass than in water and as the internal loss in glass is negligibly small, the behavior of particles in the sound field can be expected to be rather simple.

It is actually often the case, especially for organic suspensions, that the density and compressibility of a suspended particle lie near

those of a suspending liquid and the translational oscillation and deformation of the particle in the sound field must be taken into consideration. It is this more general case which was investigated by us. In the present investigation, the attenuation was measured for suspensions of polymethyl methacrylate powder. Since this material is perfectly spherical in shape and, moreover, its physical properties can be well examined in bulk phase, it satisfies reasonably well the requirement for the test of the theory. This material seems very appropriate also for the study of the effect of internal loss of suspended particles on the attenuation, which has never been discussed in the existing reports.

§ 2. Nomenclature

- α : Total amplitude attenuation coefficient in suspension
- α_1 : Attenuation coefficient in suspending liquid
- α_p : Attenuation coefficient for suspended particles $\alpha_p \equiv \alpha - \alpha_1$
- α_s : Attenuation coefficient due to scattering of sound
- α_v : Attenuation coefficient due to viscous drag at surface of particles
- α_i : Attenuation coefficient due to internal loss of particles
- c : Volume fraction of particles in suspension
- a : Radius of particles
- ρ_1, ρ_2 : Density of suspending liquid and suspended particle respectively,

$$\sigma \equiv \rho_2 / \rho_1$$
- K_1, K_2 : Adiabatic compressibility of liquid and particle respectively,

$$\tau \equiv K_2 / K_1$$
- η_1, η_2 : Shear viscosity of liquid and particle respectively
- κ_1, κ_2 : Volume viscosity of liquid and particle respectively
- V_1, V : Sound velocity in liquid and suspension respectively
- k : Propagation constant of sound (compressional wave) in suspension

$$k \equiv 2\pi f / V$$
- β : Propagation constant of transverse wave in liquid

$$\beta \equiv (\pi f \rho_1 / \eta_1)^{1/2}$$

- f : Frequency of sound
- V_l, V_t : Velocity of longitudinal and transverse waves in particle respectively
- α_l, α_t : Absorption coefficient of longitudinal and transverse waves in particle respectively.

§ 3. Experimental

The attenuations were measured in this research by a pulse technique (see block diagram, Fig. 1). A barium titanate transmitter of 3 cm diameter was excited by a high frequency pulse for the duration of several microseconds, the repetition rate of pulses being about one kilocycle. Acoustic energy passes through the suspension to a receiver, which is also a barium titanate transducer of the same size as the transmitter. The transmitter and receiver were fixed at a distance of 10 cm, their faces being set accurately parallel by a block gauge.

The received signal was attenuated by a variable attenuator (0–50 db in steps of 0.2 db), amplified by a fixed amount and displayed on an oscilloscope. The increase in the attenuation due to the addition of the particles was compensated by the variable attenuator so as to regain the original pulse height. The value of α_p was then obtained from the reading of the attenuator. Adding the particles to the liquid in approximately equal quantities and taking a series of measurements after each addition, α_p could be determined as a function of concentration.

It should be noticed here that the density and sound velocity of the suspension depend on particle concentration,⁷⁾ so that the efficiency as well as the directional characteristics of both the transmitter and receiver might vary in the course of one run of experiment. In the present experiment, however, the transmitter used was of sufficient cross section to insure a well collimated wave through the medium and the receiver was placed in the Fresnel region of sound field, hence the variation of directional characteristics could be safely neglected. The correction for the variation of efficiency of the transducers was estimated from the theory of transducers⁸⁾ as less than one percent of the observed attenuation and also ignored.

A glass tank of 11×8 cm² base and 10 cm depth was used as a container. In order to

Fig. 1. Block diagram of electronic apparatus.

obtain a uniform concentration of particles throughout the medium, the suspension was continuously stirred at an optimum speed. When the speed was too high, air bubbles were dragged into the suspension. When too low, on the other hand, sedimentation or floatation of particles occurred. Measurements in ethyl alcohol medium showed that the turbulence caused by stirring had no effect on the attenuation at the optimum stirring. All the measurements were carried out at room temperatures from 15° to 20°C. The temperature dependence of the attenuation coefficient was found within the experimental accuracy in this temperature range.

§ 4. Suspension

Commercially produced powders of polymethyl methacrylate (PMMA) were used as suspended particles. The particles were perfectly spherical in shape under microscopic examination. The distribution of radius was determined from microphotographs of about one thousand individual particles. There was a wide range of particle size, as is indicated by Fig. 2, where the number percent of particle in each radius interval of 5 microns is plotted. For the purpose of studying the particle size dependence of attenuation, some of the particles were fractionated into five fractions from the difference of sedimentation rate in ethyl alcohol, the fraction of the smallest size being not used because of extremely small amount. Except in the study in § 8, however, unfractionated particles were employed throughout this investigation.

In Table I, two sorts of average radius, $\langle a \rangle_s$ and $\langle a \rangle_v$, which are necessary to the numerical evaluation of the theories, are com-

Fig. 2. Particle radius distribution of polymethyl methacrylate powder: (a) unfractionated, (b) fractionated samples.

Table I. Average radius of particle (micron).

	Unfractionated	Fractionated				
		A	B	C	D	
$\langle a \rangle_s$	40.3	47.0	39.6	28.2	21.3	
$\langle a \rangle_v$	31.7	42.7	33.2	24.6	17.4	

puted from the distribution curve by the following definitions respectively:

$$\langle a \rangle_s = (\sum c_i a_i^3 / \sum c_i)^{1/3} = (\sum n_i a_i^6 / \sum n_i a_i^3)^{1/3} \quad (1)$$

and

$$\langle a \rangle_v = (\sum c_i a_i^{-1} / \sum c_i)^{-1} = (\sum n_i a_i^2 / \sum n_i a_i^3)^{-1}, \quad (2)$$

where c_i is the volume fraction of particles of radius a_i , n_i the number fraction.

The values of density, adiabatic compressibility and volume viscosity* of PMMA are

* The term "viscosity" in a solid is here used as the imaginary part of complex modulus divided by $2\pi f$. "Compressibility" expresses here the reciprocal of the real part of complex bulk modulus.

also to be estimated for evaluation of the theoretical formulae. These were determined by use of a PMMA plate. PMMA plate and powder probably have different polymerization degree, since the method of polymerization differs in them. But, as is well known, mechanical behaviors of a polymer in the glassy state is very nearly independent of polymerization degree.

The density was determined by the floatation method. The result obtained is $\rho_2=1.19$ g/cm³.

For the purpose of estimation of adiabatic compressibility, velocities of longitudinal and transverse waves were measured at 1.08 Mc/s by the total reflection method⁹⁾ using a PMMA plate immersed in carbon tetrachloride. The results are $V_l=2650$ m/s and $V_t=1240$ m/s. From these data adiabatic compressibility can be calculated by eliminating shear modulus G_2 from the following relations:

$$\rho_2 V_l^2 = \frac{1}{K_2} + \frac{4}{3} G_2, \quad \rho_2 V_t^2 = G_2. \quad (3)$$

The present data yield a value of $K_2=1.70 \cdot 10^{-11}$ cm²/dyne.

In order to obtain a value of volume viscosity in PMMA, the absorption coefficients of longitudinal and transverse waves in a PMMA plate was measured, inserting the plate into the sound path in a water tank. At the normal incidence of sound beam from water into the plate, only longitudinal wave is excited in the latter, and from the insertion loss corrected for the reflection loss at the interfaces one can easily obtain the absorption coefficient of longitudinal wave. On the other hand, when the incident angle is larger than the total reflection angle of longitudinal wave, transverse wave alone is transmitted in the plate. For the case at hand, i.e. PMMA plate in water, the reflection at the interfaces is reduced to nearly zero at an incident angle of ca. 50°, ¹⁰⁾ hence the absorption coefficient of transverse wave can directly be obtained. From the absorption coefficients, volume viscosity is calculated by the following relations:

$$\alpha_l = \frac{2\pi^2 f^2}{\rho_2 V_l^3} \left(\kappa_2 + \frac{4}{3} \eta_2 \right), \quad \alpha_t = \frac{2\pi^2 f^2}{\rho_2 V_t^3} \eta_2. \quad (4)$$

Since the absorption coefficients markedly vary with frequency, ultrasonic waves of the

same frequency must be used in measurements in the plate and the suspension in order to make a reasonable comparison. In the present case, it was observed at 1.08 Mc/s that $\alpha_l=0.115$ cm⁻¹ and $\alpha_t=0.613$ cm⁻¹, hence $\kappa_2=50$ poise. In the above experiments one must use a plate of thickness more than a half pulse length in order to avoid a possible error from multiple reflection of sound in the plate. A plate of 2.2 cm thickness was employed in our case.

As suspending liquids, methyl alcohol and carbon tetrachloride were employed. PMMA particles, when added, immediately disperse in these liquids and no swelling was observed at least for the period of one run. Since the density of PMMA lies between those of the two liquids, their mixture in a proper ratio, about 50 to 50 in volume, has the density equal to PMMA. In this case an appreciable swelling of particles was observed in one hour or so, hence the experiment was performed within this time.

The numerical values of density, sound velocity and adiabatic compressibility in these liquids were compiled from Sacher's paper¹¹⁾ and the International Critical Tables.

§5. Concentration Dependence of Attenuation

The values of α_p for suspensions in ethyl alcohol, carbon tetrachloride and their mixtures were obtained at six frequencies, 1.08, 1.61, 2.20, 3.24, 4.12 and 5.40 Mc/s, as a function of concentration. An example of concentration dependence of α_p is shown in Fig. 3.

Fig. 3. Concentration dependence of attenuation at 3.24 Mc/s. x denotes volume fraction of carbon tetrachloride in ethyl alcohol.

The general behavior is the same at other frequencies. Since in most cases α_p varies linearly with particle concentration over the range observed, it is to be expected that the scattering of sound from particles is single, not multiple in this range at least and the attenuation is additive with respect to the number of particles. Sometimes, especially at high frequencies, there is some indication that the curves level off at high concentration, probably due to the multiple scattering and other interactions among particles. In the following sections the value of α_p/c obtained from the linear portion of the α_p vs. concentration plot is indicated and compared with theories.

§ 6. Frequency Dependence of Attenuation and Scattering Loss

The frequency dependence of α_p/c for unfractionated particles in two liquids is indicated in Fig. 4.

The origin of the sound attenuation in a suspension has been ascribed, among others, to the scattering of sound beams from particles. The attenuation coefficient due to the

scattering from elastic spheres free to move in a non-viscous liquid has been theoretically derived by Rayleigh¹⁾ and Epstein¹²⁾ as

$$\alpha_s = \frac{k^4 a^3}{8} \left\{ \frac{4}{3} (1-\tau)^2 + \left(\frac{\sigma-1}{\sigma+1/2} \right)^2 \right\} c \quad (5)$$

under the condition $ka \ll 1$. For a polydisperse system, it is theoretically required to replace a by the average radius $\langle a \rangle$, defined by the formula (1). In Fig. 4, theoretical values of α_s/c are given in broken lines evaluated using the numerical values obtained in § 4. For both liquids the experimental curve is in very good agreement with the theoretical one near the frequency of 2 Mc/s, corresponding to about $ka=0.5$, i.e. the radius being of the order of one tenth of the wave length. But at higher frequencies the experimental curve lies fairly below the theoretical one and at lower frequencies the former is far above the latter.

Since Eq. (5) is valid only under the assumption $ka \ll 1$, the discrepancy between the theory and experiment at high frequencies may be ascribed to the failure of this assumption. In fact, when the radius of a particle approaches the wave length, the interference of the scattered waves from different parts of the particle may considerably diminish the scattered energy. From the above reasons it may be concluded that the scattering loss is a predominant factor of the attenuation in suspensions at frequencies above 2 Mc/s in this experiment. Additional confirmations of this conclusion will be provided in the following two sections.

§ 7. Effect of Suspending Liquid on Attenuation

The effect of a suspending liquid on α_p/c was measured at the frequency of 3.24 Mc/s, where the scattering loss is expected to be predominant. The results are illustrated in Fig. 5, together with the theoretical curves calculated from Eq. (5).

In the case of ethyl alcohol—carbon tetrachloride system, both liquids having good affinity to PMMA, the experimental curve has a quite similar behavior to the theoretical one, disregarding that the latter is always about twice larger than the former, probably due to the reason described in the last section.

Fig. 4. Frequency dependence of attenuation: experimental values of α_p/c in ethyl alcohol (O) and carbon tetrachloride (●). Broken lines indicate theoretical value of α_s/c in ethyl alcohol (below) and carbon tetrachloride (above).

Fig. 5. Effect of suspending liquid on attenuation at 3.24 Mc/s: (a) ethyl alcohol-carbon tetrachloride system, (b) ethyl alcohol-water system. Solid line indicates experimental value of α_p/c , broken line theoretical value of α_s/c .

On the other hand, in the case of ethyl alcohol—water system, the latter having only poor affinity to PMMA, the experimental value very rapidly increases with volume fraction of water. This may be due to the incomplete deflocculation of particles in the liquid. The association of particles should increase the effective radius, so make rise to the attenuation, as is readily known from Eq. (5). In fact, the association of PMMA particles in water was observed by a microscope and an appreciable decrease in the attenuation was found for the aqueous suspension of PMMA particles after violent stirring for an hour.

§ 8. Dependence of Attenuation on Particle Radius

Fig. 6 shows the attenuation for ethyl alcohol suspensions of fractionated and unfractionated particles at the frequency of 3.24 Mc/s, together with the theoretical curve calculated from Eq. (5). The accuracy of the data presented here is somewhat less than the others because the available amount of the fractionated particles were rather limited.

Fig. 6. Dependence of attenuation on particle radius at 3.24 Mc/s: ethyl alcohol suspensions of (A, B, C, D) fractionated and (E) unfractionated particles. Solid line indicates experimental value of α_p/c , broken line theoretical value of α_s/c .

As is easily seen, the experimental curve is nearly of the same form as that of the frequency dependence given in Fig. 4. It is apparent from Eq. (5) that increasing the fre-

quency has the same effect on the scattering loss as increasing the particle radius. In Fig. 6, the accord between experiment and theory is encountered for the radius of 25 microns, corresponding to a value of $ka=0.5$, which is in good agreement with the case of the frequency dependence.

§9. Attenuation in Low Frequency Range

As has been described in the preceding sections, the scattering of sound from suspended particles is considered as a dominant origin of the attenuation for the frequency range of $ka>0.5$. Below this frequency, however, the observed attenuation is appreciably larger than that predicted from the scattering theory (see Fig. 4), hence there must exist some other origins of attenuation, which, at high frequencies, may become negligible compared with the scattering loss.

In this relation, Lamb,²⁾ Epstein¹²⁾ and Urick³⁾ calculated the energy loss due to the viscous friction at the surface of a sphere, so-called "viscous loss", and obtained for the attenuation the formula

$$\alpha_v = \frac{k}{2} (\sigma - 1)^2 \frac{S}{S^2 + (\sigma + T)^2} c, \quad (6)$$

where

$$S = \frac{9}{4\beta a} \left(1 + \frac{1}{\beta a}\right), \quad T = \frac{1}{2} + \frac{9}{4\beta a}.$$

When $\beta a \gg 1$, that is, viscous shear wave in the liquid damps out very rapidly as is our case, the above equation is simplified as

$$\alpha_v = \frac{9k}{8\beta a} \left(\frac{\sigma - 1}{\sigma + 1/2}\right)^2 c. \quad (7)$$

For a polydisperse system a in Eq. (7) must be replaced by $\langle a \rangle_v$ defined by Eq. (2).

Recently, Lane¹³⁾ calculated another type of viscous loss caused by the acoustic streaming from an oscillating sphere. But this type of viscous loss was found to be extremely small in our case, so will no more be referred to in this paper.

Busby and Richardson⁵⁾ in aqueous suspensions of glass spheres found good agreement between experiment and theory, considering the scattering and viscous loss. In the present study, however, the situation is more complicated. Since PMMA has much higher internal viscosity than the suspending liquids, the absorption of sound due to the internal viscosity becomes of great significance. In

fact, the absorption coefficient of longitudinal wave is 0.11 cm^{-1} in PMMA, but only 0.005 cm^{-1} in carbon tetrachloride at 1 Mc/s .

No theory for the sound attenuation in a suspension of viscoelastic particles has been developed as yet. Here we assume for simplicity that, firstly, the particle radius is much smaller than the wave length, i.e. $ka \ll 1$, and secondly, the particle oscillates perfectly in phase with the surrounding liquid, so that there exists no relative translational motion between them. The first assumption is of course valid in such low frequencies as in the present case. The second assumption is fulfilled if the density is the same for the particle and the liquid,³⁾ a condition also nearly satisfied in our case.

As is well known, generally a material in the field of longitudinal wave undergoes dilatation as well as shear. But in a suspension, since a particle has rigidity and a liquid none, the former undergoes no shear, but dilatation alone. Under these conditions a suspended particle in the sound field is expected to be applied by uniform pressure equal to a surrounding liquid and from a simple calculation⁷⁾ the compressibility of a suspension K is found to have an additive character in volume:

$$K = K_1(1 - c) + K_2c.$$

For a viscoelastic medium, compressibility becomes a complex quantity, so its imaginary part, and therefore the voluminal part of absorption coefficient per unit wave length, should also have an additivity.

From the above considerations the absorption coefficient per wave length in a suspension is approximated by

$$\frac{\alpha V}{f} = \frac{\alpha_1 V_1}{f} (1 - c) + \left(\text{voluminal part of } \frac{\alpha_1 V_1}{f} \right) c. \quad (8)$$

It should be noted that, since there may exist additional shear motion of liquid at the surface of particle due to the discontinuity of rigidity, the shear viscosity term in $(\alpha_1 V_1/f)$ must somewhat be modified from the case of homogeneous liquid. This effect, however, is neglected here because the particle radius is much smaller than the wave length. Anyway, the first term in the righthand side of Eq. (8) plays a rather limited role in the fol-

lowing deduction.

The absorption coefficient per unit length therefore becomes

$$\alpha = \alpha_1 \frac{V_1}{V} (1-c) + \frac{2\pi^2 f^2 \kappa_2 K_2}{V} c$$

$$\doteq \alpha_1 + \left(\frac{2\pi^2 f^2 \kappa_2 K_2}{V_1} - \alpha_1 \right) c.$$

Hence the contribution of suspended particle is obtained as

$$\alpha_i = \alpha - \alpha_1 \frac{V_1}{V} = \frac{2\pi^2 f^2 \kappa_2 K_2}{V_1} c. \quad (9)$$

In the above derivation, the approximations were employed that $\alpha_1 \ll$ (voluminal part of absorption coefficient in particle) and $V \doteq V_1$. V was computed by use of Urick's equation⁷⁾ as a function of concentration and the approximation was found to be reasonable in the present case.

Table II. Attenuation coefficient (cm⁻¹) at 1.08 Mc/s.

Suspending liquid: volume fraction of CCl ₄ in C ₂ H ₅ OH (%)	Observed value of α_p/c	Calculated value			
		α_s/c	α_v/c	α_i/c	Total
0	0.30	0.11	0.08	0.18	0.37
25	0.31	0.15	0.02	0.19	0.36
50	0.36	0.18	0.00	0.20	0.38
75	0.41	0.22	0.01	0.22	0.45
100	0.48	0.22	0.04	0.22	0.48

In Table II the experimental values of attenuation coefficient at 1.08 Mc/s are listed, together with the theoretical ones calculated from Eqs. (5), (7) and (9) respectively. The sum of the three theoretical values is in satisfactory agreement with the experimental ones within the limits of accuracy of the experiment and of the approximations of the theories.

The frequency dependence of the viscous loss and internal loss is not so strong as the scattering loss. The viscous loss is proportional only to half-power of the frequency and the frequency dependence of the internal loss is smaller than proportional to square of the frequency since the viscosity of a high-polymeric solid is a decreasing function of frequency due to the relaxational effect. At high frequencies, therefore, the loss in these fashions may be well covered by the scattering loss, so the conclusion that the attenuation at high frequencies can be explained in terms of scattering alone may little be influenced by taking into consideration the viscous and internal loss.

In the study of viscoelastic behavior or high polymers, measurements of dynamic bulk modulus and volume viscosity have a great significance.¹⁴⁾ The bulk modulus can be obtained, as described by Urick,⁷⁾ from the measurement of sound velocity in suspen-

sions of the material to be studied. The method used in this research can be employed to measure the volume viscosity, if spherical particles of the material can be obtained in an appropriate radius.

§ 10. Conclusion

Specific conclusions to be drawn from this research are the following:

(1) The attenuation coefficient of sound in suspensions depends linearly on the concentration of suspended particles in the range of concentration up to several percents.

(2) At high frequencies ($ka > 0.5$), the scattering and reflection of sound from suspended particles are the major causes of attenuation. At these frequencies, however, the experimental value of attenuation lies markedly below the theoretical one predicted from Rayleigh's equation, which is established for $ka \ll 1$.

(3) At low frequencies ($ka < 0.5$), the scattering plays a role of relatively decreasing importance and the viscous absorption term as well as the loss due to the internal viscosity of particles must be considered. The sum of these three effects gives satisfactory agreement with the experiment.

(4) In the low frequency range where the internal loss predominates, the method employed in this research can be used to measure

the volume viscosity of a solid material.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 11, NOVEMBER, 1958

On the Limit of Superheat

By HIROMU WAKESHIMA and KAZUO TAKATA

Kobe University of Mercantile Marine, Kobe

(Received July 9, 1958)

A new method of observing the limit of superheat was devised, in which small drops of a sample liquid are heated as they rise up in the non-soluble heating liquid with a suitable temperature gradient upward. Using the method, the limit of superheat was determined, mainly for some saturated hydrocarbons and polymethylenes. The result was compared with Döring's theory of spontaneous bubble formation in superheated liquids. The agreement between the theory and experiment was satisfactory, which seems to throw some light upon the problem of surface free energy on the nuclear bubble.

§ 1. Introduction

The limit of superheat is interesting from the standpoint of research on nucleation, because the rate of homogeneous nucleation for bubble formation can be evaluated theoretically in the case of superheat¹⁾ as in the case of condensation in supersaturated vapors, so far as we assume macroscopic values for the surface free energy on the boundaries of nuclei. As for reliable experimental facts

which can be compared with the theoretical conclusion, however, only observations by K. L. Wismer and his collaborators²⁾ have been available up to the present. This situation may probably be due to the difficulty of obtaining reproducible results, owing to gas cavities on the wall of the container of the liquid in question, which are liable to act as sources of heterogeneous nucleation. Recently L. Trefethen³⁾ has shown that liquids can

easily be superheated when they are surrounded by other liquids. (i.e. they are not in contact with solids) But he failed to observe the limit of superheat of the liquids he investigated, because of his experimental conditions. Encouraged by his observation, we devised a new method of observing the limit, by which rather a definite limit of superheat has been obtained for some liquids. Here will be given the experimental procedure, the results obtained and their comparison with the expectation from the theory of homogeneous nucleation for bubble formation in superheated liquids and some discussion on this problem will be made.

§ 2. Experimental Procedure

The principle of our method is as follows: The vertical tube containing the suitable liquid which practically does not dissolve a sample liquid and which has a larger density and sufficiently higher boiling point than that of the liquid in question, is heated at the upper end and a stable, vertical temperature gradient is maintained in the column of the heating liquid. Through a small hole on the container of the liquid at the lower end of the column, small drops of the specimen is suitably introduced and the height, at which the drops, in rising up the column, reaches the limit of superheat for the liquid and explode, is measured.

Fig. 1 shows the general scheme of the equipment used. The container of the heating liquid, made with a glass tube of about 35 cm in length, 2 cm in outer diameter, is surrounded by a brass pipe, 20 cm long, 1 mm thick and of about 2.5 cm in outer diameter, which is fixed coaxially to the container. The pipe has blackened inside and its outside is polished. Two vertical slits were suitably cut along the pipe, one for illumination of the central part of the heating column and the other for observation of this part from outside. The upper part of the brass pipe can be kept at various constant temperatures, using the electric heater wound up on the pipe and supplied by a stabilized power source. The heating column with the brass pipe outside, is enclosed air tight in another coaxial glass tube, of about 3.5 cm in diameter, the lower end of which is closed with a metallic hollow stopper, and the space between the

two glass tubes is evacuated, in order to prevent heat conduction radial to the heating column. Water at constant temperature from a big reservoir flows inside the stopper at constant speed, controlled by the overflow device. The heating liquid is sucked up by a suction pump, from the beaker through a small hole, of about 1 mm in diameter, into the container until its surface is raised somewhat above the heater. To keep the height of the surface constant, the air leak is effectively used, together with the large flask and the narrow capillary tube, inserted between the container and the suction pump. When the current through the heater and the height of the heating liquid column remain unchanged, we can maintain in the heating column a stable temperature slope, e.g. from about 250°C down to room temperature, as we confirmed it using a thermo-couple. The guide tube, made of glass, is to guide the sample droplets below the hole of the container. To produce small drops of a sample liquid, the latter was poured into the guide tube about one centimetre thick over the heating liquid and then a small quantity of either the heating liquid or the specimen was injected, with a syringe having a glass nozzle, against the interface between the sample and the heating liquids. After a little preliminary exercise, we could manage to let drops of suitable sizes (usually about 20 μ to 200 μ in diameter) leak out of the nozzle of the guide tube, to such a degree that some of the drops occasionally passed through the hole into the container of the heating liquid. The drops, in rising up the heating column, are illuminated against dark back-ground by a lamp and a cylindrical lens and are observed directly with naked eyes or through a cathetometer when it is needed. In order to know the size of droplets, the time required by droplets to ascend a definite distance was measured with a stop-watch and the radii of the droplets were calculated, using Stoke's law of resistance for a liquid sphere moving uniformly in stagnant fluid. When the droplet reaches the superheat limit and vaporize in an instant, it suddenly lights up brighter with a small cracking sound and begins to ascend faster than before. So we can easily locate the point of explosion.

The materials, of which we investigated the

Fig. 1.

limit of superheat, were mostly saturated hydrocarbons and polymethylenes of the highest quality, purified by Phillip Petroleum Company or Maruzen Petroleum Company. Namely the purity of *n*-pentane, *n*-hexane, isopentane, cyclopentane and methylcyclopentane supplied by Phillip Petroleum Company was between 99.99 to 99.67 in mol-percent, while *n*-heptane and cyclohexane specimens were distilled by Research Institute of Maruzen Company, within the temperature range less than 0.1°C. The corresponding heating liquid was pure sulfuric acid. We also made investigation on

ethyl ether of extra pure grade obtainable on the market. As for the heating liquid in this case, glycerin and ethylene glycol were used.

§ 3. Experimental Results and Comparison with Theory

The most remarkable fact observed thus far was that the limit of superheat was pretty definite. Especially in cases of saturated hydrocarbons and polymethylenes in sulfuric acid, almost all of about fifty observed droplets in each case exploded within narrow ranges of about 1 mm width, irrespective of

the size of drops. (in most cases the largest was almost hundred times the smallest in volume) In the cases of ethyl ether in glycerin and ethylene glycol, though the majority of droplets exploded at first within a rather narrow range of few millimetres, there were undoubtedly some which exploded prematurely without any apparent reason. And, possibly because of the slight solubility of ether in these heating liquids, the condition in the column seemed to change as the specimen drops were sent into the heated container for some time; by and by there appeared droplets which did not show any sign of superheating. Larger viscosity of, and the solubility in, the heating liquids compelled us to work with larger drops in these cases (~ 0.6 mm in diameter), which fact caused difficulties and might have led to various errors.

In the following Table I, will be listed boiling points, explosion temperatures and the

Table I.

Material	boil. p.	expl. temp.	limit of superheat exper.	theoret.
n-pentane	36.1°	146°	110°	110.4°
n-hexane	68.7°	182°	113°	111.6°
n-heptane	98.4°	211°	113°	114.4°
isopentane	27.8°	138°	110°(107°)	109.3°
cyclopentane	49.3°	180°	131°	128.7°
methylcyclopentane	71.8°	200°	128°	125.2°
cyclohexane	81.1°	216°	135°	138.2°
ethyl ether	34.6°	147°	112°(108°)	109.4°

corresponding limits of superheat obtained in this experiment, together with the theoretical conclusion according to Döring's formula which will be explained afterwards. Values observed by Wismer are also given in bracket for comparison.

In calculating superheat limits theoretically, the formula given by W. Döring

$$J = Z_1 e^{-\lambda/kT} \{6\sigma/(3-b)\pi m\}^{1/2} \times \exp \{-16\pi\sigma^3/3kT(p_k - p_1)^2\} \quad (1)$$

was used, where J denotes the time rate of homogeneous nucleation in a droplet containing Z_1 molecules. As for the size of droplet, we adopted in this calculation the value 0.1 mm for the diameter. λ means the heat of vaporization per molecule, σ the surface tension and m the molecular mass of the liquid in question. b stands for $(p_k - p_1)/p_k$, in which

p_k and p_1 represent the pressure inside the nuclear bubble and that acting upon the bubble from outside respectively. k and T have the usual meaning. The limit of superheat is supposed to be corresponding to the temperature at which $J=1$; this assumption will be permissible in view of the extremely great dependence of J -value on the temperature, as will be seen from Table II which shows an example of such a relation. (n-pentane)

Table II.

Temperature	J -value
140°C	6.37×10^{-25}
145°C	2.39×10^{-4}
150°C	5.89×10^7

Values of physical constants necessary for the calculation refer to those given in "International Critical Table", "Timmerman's Physico-Chemical Constant of Pure Organic Compounds" and others⁴. Specifically, values of surface tension for the liquids in the temperature range near the explosion temperatures, which are most relevant to the limit as will be discussed later, and yet which are not given in any literature, were calculated using Kata-yama's formula for the temperature dependence of surface tension⁵, from the values at lower temperatures.

§ 4. Discussions

In estimating the experimental errors for the determination of superheat limits, we have to take into account various factors. Though the spots at which droplets explode can be located within the error of a few tenth millimetres, assigning a temperature to each exploding droplet is open to some sources of errors.

First, the explosion of a droplet and the rapid rise of the bubble thereafter might be suspected, inevitably to disturb the temperature distribution of the surroundings which would influence the next explosion. Nevertheless, for the tiny droplets used in our experiment where one explosion took place after the interval of at least thirty to forty seconds from the preceding one, this kind of influence is negligible. That the location of explosion did not disperse for a given condition shows this facts.

Second, in the preliminary measurement of

the temperature distribution in the heating column, we had to insert the thermo-couple along the axis of the column from above, i.e. along the slope of temperature, because of the structure of our apparatus. We noticed that this condition possibly brings about a serious error in the determination of temperature at the spot of thermo-junction, unless a thin couple with a larger joint than a usual one is not used. We used a thermo-couple consisting of a constantan wire of 0.3 mm in width and a copper wire 0.15 mm wide covered with a glass capillary, and having at the junction a copper ball, about 1 mm in diameter. When this couple, enclosed in a thin glass tube, was put in reverse directions in the heating column (in a similar column as the one used in the main experiment, but which was made to permit the couple to be inserted from the bottom as well as from the top), it showed temperature differences of $2^{\circ}\sim 3^{\circ}\text{C}$, according to the magnitude of temperature gradient in the surrounding liquid column. From these differences we evaluated the necessary correction to the temperature measured.

Third, the temperature of rising drops might be somewhat lower than that of the surroundings. It would be difficult to calculate the lag of temperature rise vigorously. In a rough estimation of its order of magnitude, we neglected the heat conduction inside the droplet and assumed a stationary heat flow outside of, and spherically symmetric to, the droplet, corresponding to the temperature difference between the droplet and the point distant from it. Then it is easy to derive a formula $\Delta\theta = (r^2/3\kappa)\alpha v$ where r , κ , α and v denote the radius of the droplet, the thermal diffusivity, the temperature gradient and the rising speed of droplet respectively. For the condition in this experiment, $\Delta\theta$ came out to be of the order of magnitude a few tenth degrees centigrade. (except for the case of ethyl ether)

In short, considering various factors mentioned above, we have estimated the error for the cases of saturated hydrocarbons and polymethylenes to be about 1°C and that for the case of ethyl ether not much larger than 5°C .

As for the theoretical values, we cannot estimate the limit of error for sure. Particular we are not certain how accurate Ka-

tayama's formula is in predicting surface tension at higher temperatures in question here. Judging from the dispersion of extrapolated values when reference surface tensions at different sets of temperatures were used, we are not likely to be free from errors less than a few percent in the values of surface tension. Then our theoretical values might have errors of one or two degrees at least.

Now the question might be raised whether the limits of superheat we observed actually correspond to the spontaneous formation of bubbles in the liquid themselves, i.e. to the homogeneous nucleation, or the bubble formation took place on the boundary of droplets, namely it corresponds to the heterogeneous nucleation. In this connection it is interesting to notice the agreement of our result for isopentane with that given by Wismer. The fact that these two cases were in good accordance, in spite of very different nature of the boundaries of the specimen, seems to indicate clearly that the explosion of droplets was due to bubble formation by homogeneous nucleation. In evitable existence in this experiment, of motes and dissolved molecules of ambient liquid in the droplets was not likely to have conspicuous influence upon the superheat limit, as such a conclusion was already drawn by Wismer.

If all the limits of superheat observed in this experiment actually correspond to the homogeneous nucleation, then the remarkable agreement between the observed limits and the calculated, shown in Table I, gives another strong evidence that Döring's theory is applicable to the spontaneous bubble formation in superheated liquids, in spite of the difficulty of a bubble model of nucleus from statistical mechanical point of view. (for bubbles of the order of magnitude 10^{-7} cm in diameter) Moreover, it means, at least for the liquids investigated here, surface free energy on the boundaries of nuclear bubbles does not differ much from that of the macroscopic vapor-liquid boundaries. Because, according to the calculation mentioned above, the change of five percent of surface tension corresponds to the change of one to two degrees centigrade of the superheat limit, i.e. to the limit of error for observation as well as calculation.

Acknowledgement

The authors wish to express their sincere

thanks to Professor Itsuro Uhara of Kobe University for his valuable discussions on this problem, and to Mr. Tsunehide Kôzuma of Maruzen Petroleum Company for his kind donation of saturated hydrocarbon and polymethylene specimens of high purity. Their thanks are also due to Miss Hiroko Yamamoto for her help in calculating the superheat limits for various liquids.

Etch Pits of Sb Single Crystals

By Jiro SHIGETA and Makoto HIRAMATSU

*Department of Physics, Okayama
University, Okayama*

(Received July 25, 1958)

Chemical as well as thermal etch pits of Sb single crystals prepared by zone-melting were studied in connection with dislocations. The Sb ingot used is analysed as 99.42 wt. % Sb, 0.225 S, 0.025 Cu, 0.006 Bi, 0.022 As, 0.192 Fe and only a trace of Zn. Cleavage faces of Sb single crystals were etched by etching reagent (consisted of 10 g FeCl₃, 30 cc HCl and 120 cc H₂O) at temperatures from 25 to 45°C for one to several minutes. The density of etch pits ranges from ca. 1×10^6 to ca. $2 \times 10^7/\text{cm}^2$, the latter of which corresponds to heavily strained crystals.

At the initial stage of etching the shape of each pit is a shallow regular-trigonal-pyramid and the progress of etching causes the following peculiar changes in each pit: the eccentricity of the pit-core, the formation of irregular pit contours and the growth of steps on pit sides. In an electron micrograph the shape of each pit-core is a simply conical dimple without any particular structure.

#1. When a cleavage face of a single crystal is etched progressively, the site of each pit is almost fixed throughout the whole etching period. Further, when the originally etched cleavage face is cleaved off by the thickness of about 20μ and the

These facts indicate that through each etch pit a line singularity particularly sensitive to etching continues into the crystal.

#2. The etch pits can be closely matched on the pair of separated faces of a cleft crystal as shown in Fig. 1.

#3. A single crystal, annealed at 520°C for several to several tens hours, reveals regular etch-pit arrays on sub-boundaries.

#4. The etching of a cleavage face previously scratched quickly and finely by a steel needle reveals, besides incidental pits, etch-pit arrays lined up on many straight lines parallel to $\langle 110 \rangle$ directions. The similar etch-pit arrays can be observed frequently on cleavage faces of Sb single crystals bended or pressed.

#5. When a cleavage face of a single crystal is thermally etched at ca. 400°C in vacuum of 10^{-2} to 10^{-4} mm Hg for several minutes, fairly well defined etch pit or etch-pit arrays can be observed as well. Etch-pit arrays thus revealed on sub-boundaries by thermal and chemical etching correspond qualitatively to one another, while quantitatively the etch pit density of the former is far lower than that of the latter.

These experimental results #1~4 suggest that chemical etch pits thus developed on cleavage faces of Sb single crystals are due to dislocations emerging from the grains and one to one correspondence between dislocations and etch pits may be expected. Thus, by means of chemical etch pits it is possible to observe the distribution of dislocations in Sb single crystals. On the other hand, the result of thermal etching #5 seems to show that thermal etch technique such as reported by Hendrickson and Machlin¹⁾ cannot be applied successfully to Sb single crystals because of its high vapour pressure at high temperature²⁾. Details of this investigation will be published later elsewhere.

The authors wish to express their gratitude to Professor Sho Yoshida for his valuable discussions.

renewed cleavage face is etched afresh, etch pits on both cleavage faces correspond to one another.

J. PHYS. SOC. JAPAN **13** (1958) 1405**Molecular Collisions in the Two-Dimensional Gases**

By Kazuo TAKAYANAGI

*Department of Physics,
Saitama University, Urawa*

(Received September 29, 1958)

Gases adsorbed on the surface of liquid or solid are often treated as two-dimensional gases. Especially for the van der Waals adsorption, this simplified treatment has been found fruitful¹⁾. Thus it may be worth studying the collision processes in the two-dimensional space.

The probability of scattering in the central force potential $V(r)$ can be calculated just as in the three-dimensional case. The Schrödinger equation in terms of the polar coordinates is (in the centre-of-gravity system)

$$\{-\hbar^2/2\mu r^2\}(r^2 \cdot \partial^2/\partial r^2 + r \cdot \partial/\partial r + \partial^2/\partial \theta^2) + V(r)\}\psi = E\psi, \quad (1)$$

where $E = \hbar^2 k^2/2\mu$ is the energy of the system, μ the reduced mass. For the adsorbed gas, it may be necessary to use *effective* molecular masses*. We can obtain the solution of (1) in the form $R(r)\Theta(\theta)$, where $\Theta(\theta)$ is $\sin m\theta$ or $\cos m\theta$, $m=0, \pm 1, \pm 2, \dots$. $R(r)$ is obtained by solving

$$\{r^2 \cdot d^2/dr^2 + r \cdot d/dr + (k^2 r^2 - m^2)\}R(r) = 2\mu\hbar^{-2}r^2 V(r)R(r). \quad (2)$$

For $V=0$, the proper solution is given by the Bessel function $J_m(kr)$.

Now we must obtain the solution of (1) with the asymptotic form

$$\psi \sim \exp(ikr \cos \theta) + f(\theta) \exp(ikr)/\sqrt{r}. \quad (3)$$

$dQ \equiv |f(\theta)|^2 d\theta$ is of dimension of the length and is the differential cross section in the two-dimensional collision. By making use of the well known expansion

$$\exp(ikr \cos \theta) = \sum_{m=0}^{\infty} i^m \varepsilon_m J_m(kr) \cos m\theta,$$

$$\varepsilon_m = 2 - \delta_{m0},$$

we can easily obtain

$$\psi = \sum_{m=0}^{\infty} i^m \varepsilon_m \sqrt{2/\pi} \exp(i\delta_m) R_m(r) \cos m\theta, \quad (4)$$

where $R_m(r)$ is the proper solution of (2) with the asymptotic form

$$\cos(kr - m\pi/2 - \pi/4 + \delta_m)/\sqrt{kr}.$$

The amplitude of the scattered wave is given by

$$f(\theta) = \sqrt{2/\pi k} \exp(i\pi/4) \sum_m \varepsilon_m \exp(i\delta_m) \sin \delta_m \cos m\theta, \quad (5)$$

so that the total scattering cross section is

$$Q_s = \int_{-\pi}^{\pi} |f(\theta)|^2 d\theta = (4/k) \sum_m \varepsilon_m \sin^2 \delta_m. \quad (6)$$

The phase shifts δ_m is easily calculated for the uniform potential hole as well as for the uniform potential barrier. For the rigid spheres with radius a , the phases are simply given by $\tan \delta_m = J_m(ka)/N_m(ka)$, where $N_m(x)$ is the Neumann function.

The Virial coefficients for the two-dimensional gas have been studied by Kihara²⁾ using a simplified intermolecular potential function.

Kinetic theory of the two-dimensional gases is developed along the same line as in the three-dimensional case. Maxwellian distribution in the two-dimensional case is of the form

$$(nM/2\pi\kappa T) \exp(-Mv^2/2\kappa T) dv,$$

where κ is the Boltzmann constant, M the molecular mass, and other notations as usual. Transport coefficients are also obtained without difficulty. Among others the diffusion coefficient of the binary mixture is given by

$$D_{ij} = (\kappa T/2n\mu_{ij})/A_{ij}, \quad (7)$$

where n is the total number density, μ_{ij} is the reduced mass of the colliding pair and

$$A_{ij} = \sqrt{2\kappa T/\mu_{ij}} \int_0^{\infty} \gamma^2 \exp(-\gamma^2) Q_D(\gamma) d\gamma.$$

In the integral

$$\gamma^2 = \mu_{ij} g_{ij}^2/2\kappa T, \quad Q_D = \int_{-\pi}^{\pi} (1 - \cos \theta) |f(\theta)|^2 d\theta,$$

and g_{ij} is the relative incident velocity. Substitution of (5) into the last expression gives

$$Q_D = (4/k) \sum_{m=0}^{\infty} \sin^2(\delta_m - \delta_{m+1}).$$

J. PHYS. SOC. JAPAN **13** (1958) 1406**A Note on the Magnetoresistance Effect of Strain Gauge Wire**

By Hideo TAKAKI and Toshiro TSUJI*

Department of Chemistry Faculty of Science, Kyoto University

(Received July 31, 1958)

As previously described¹⁾ the strain gauge of constantan (Ni 45%, Cu 55%) has a notable magnetoresistance effect. The electrical conductivity increases in the presence of magnetic field, while that of non-magnetic metals decreases with magnetic field. The temperature dependence of the magnetoresistance effect of the strain gauge wire is reported in this short note.

The method of measurement of the electrical resistance was the same as in the case of magnetostriction. The strain gauge bonded on copper strip was placed in magnetic fields. Copper has no magnetostriction so that only the change in electrical resistance of the gauge can be measured. To measure the magnetoresistance the method of using such a fine wire is very effective because of its high electrical resistivity.

The results obtained are shown in Fig. 1. At a

Fig. 1. Magnetoresistance effect of Constantan strain gauge at various temperatures.

constant temperature all the measured point fall on the parabolla described by

$$\frac{\Delta R}{R} = -kH^2, \quad (1)$$

k being a constant. The material used is ferromagnetic below 60°K. The tendency that the conductivity increases with magnetic field can therefore be considered to be the magnetoresistance effect of ferromagnetic metal above the Curie point.

* Present address; Nippon Electric Company Ltd., Tokyo.

We may assume that the above relation (1) can be analytically described by the following equation,

$$\frac{\Delta R}{R} = -k'I^2 = -k'\left(\frac{C}{T-\theta}\right)^2 H^2, \quad (2)$$

where k' is a constant and I is equal to the effective magnetization above the Curie point. In Fig. 2 the inverse square root of $-(\Delta R/R)/H^2$ versus absolute temperature was plotted. The plotted points composed a straight line. The Curie point is determined from the intersecting point of the straight line and the abscissa. We see a close agreement between the value thus obtained and that found by other methods.

Gerlach and Schneiderhan²⁾ measured the magnetoresistance of nickel near the Curie point and concluded that the decrease of electrical resistance with external field was proportional to the square of effective magnetization. Our results coincide

Fig. 2. Temperature dependence of magnetoresistance effect.

$H/\sqrt{-\Delta R/R}$ varies linearly with $(T-\theta)$.

well with their conclusion.

Large magnetoresistance effect causes the error in the measurement of magnetostriction. At room temperature the magnetoresistance effect of the active gauge on ferromagnetic sample is cancelled out by that of the dummy gauge. At the temperature of the boiling point of oxygen magnetoresistance effect of both gauges is too large to be compensated. The error is due to the difference of magnetic fields which act on two gauges. Actually the difference is inevitable because of the demagnetizing field on the sample. The difference between active and dummy gauges in these effects is described as follows,

$$\left(\frac{\Delta R}{R}\right)_{\text{active}} - \left(\frac{\Delta R}{R}\right)_{\text{dummy}} = -k\{(H-NI)^2 - H^2\}, \quad (3)$$

where $-NI$ denotes the demagnetizing field. This difference is positive in higher fields. Consequently the positive error is expected to intermix in the value of forced magnetostriction.

A Certain Anomalous Behavior of Iron Sulfides

By Miyuki MURAKAMI and Eiji HIRAHARA

Department of Physics, Faculty of Science,
Tohoku University, Sendai, Japan

(Received September 4, 1958)

We have experimentally studied the anisotropies of magnetic and electrical properties of iron sulfide single crystal¹⁾. We have recently found an anomalous behavior of susceptibility at a temperature somewhat lower than T_α (the temperature of α -transformation) on a cooling process.

The temperature dependences of susceptibility of single crystal on heating are shown by solid lines in Fig. 1. The curves 1 and 2 are those of the

Fig. 1. The temperature dependence of susceptibility of the single crystalline sample. The solid lines are heating curves, and the dotted lines cooling curves.

cases the external magnetic field is applied in parallel and in perpendicular to the c -axis of crystal, respectively. The sample being cooled along curve 2 from a temperature above T_α , a large peak of susceptibility has been observed at 110°C with a temperature width of about 15°C as shown by dotted lines in Fig. 1. On the other hand, the sample being cooled along curve 1, the susceptibility starts to fall at a temperature rather lower than T_α , and exhibits two steps before it settles down to the normal value. The temperature at which the anomaly occurs seems to shift lower with the rate of cooling. The results using of a polycrystalline sample have been observed as shown in Fig. 2, which should be anticipated from the results of single crystal sample.

However, so far no clear explanation of the anomalous behavior have been obtained, it may be provisionally understood as follows. According to

Fig. 2. The temperature dependence of susceptibility of the polycrystalline sample. The solid line is heating curve, and the dotted line cooling curve.

the X-ray measurements²⁾, the stoichiometric iron sulfide contracts abruptly along c -axis on heating. We have been also observed the same results by using of a interferential dilatometer, and observed a hysteresis phenomenon on cooling. Connecting with the hysteresis phenomenon of lattice, we assume a change of exchange energy on the cooling process take place at a temperature lower than T_α , but a change of anisotropy energy just at T_α . According to our previous works¹⁾, the preferred direction of spins is on c -plane at the temperatures above T_α , and is along c -axis below T_α . When the sample is cooled along curve 2, the susceptibility abruptly increases with the change of anisotropy energy at T_α , and after that it decreased to the normal value because of the increase of exchange energy. When the sample is cooled along curve 1, although the change of anisotropy energy takes place at T_α the susceptibility would keep a considerable value because of the small value of exchange energy, and then, it starts to decrease after the increase of exchange energy.

The studies of these anomalous behavior seem to give a light to an elucidation for the nature of α -transformation, and so they have been required the more detailed measurements, which will be soon reported on another paper by the one of authors.

J. PHYS. SOC. JAPAN **13** (1958) 1408~1409**On the Mechanical Loss of Polyethylene**

By Yasaku WADA

*Department of Applied Physics, Faculty of
Engineering, University of Tokyo,
Bunkyo-ku, Tokyo*

(Received August 14, 1958)

During the past several years many reports¹⁻¹⁴⁾ have been published on the temperature variation of dynamic mechanical loss factor of polyethylene and it has been quite firmly established that for branched polyethylene there exist three loss peaks below the melting point. It is customary to label these peaks as α , β and γ descending from higher temperatures. For unbranched polyethylene, i.e. polyethylene of high crystallinity, it has been observed^{8,9,11)} that the α peak shifts to high temperatures, the β disappears and the γ remains unchanged. The whole set of these investigations covers the frequency range from 10^{-1} to 10^7 cps and makes it

possible to illustrate the "transition map", which is presented in this short note.

Fig. 1 represents this transition map, giving the frequency used in the measurement in logarithmic scale against the reciprocal of absolute temperature of observed loss maxima. In Fig. 1, numbers beside each point refer to the reference at the end of this note.

While each observed point in Fig. 1 has been obtained by use of different specimens and different modes of vibration, almost all the points lie near a straight line for each transition respectively. A large deviation from the line is found only in the data of Schmieder-Wolf and Butta. Neglecting these exceptions, the gradient of the lines gives apparent activation energy of 40, 30 and 9 kcal/mol for α , β and γ transitions respectively. For the α transition the data are still too scanty for the precise evaluation of activation energy.

The discussion about the molecular mechanism associated with these loss peaks is beyond the scope of this short note.

Fig. 1. Relation between temperature of mechanical loss maxima and frequency of measurement for branched and unbranched polyethylene. (* above this temperature)

length λ_p was assumed to be 0.025 mm ($s=522$ cm/sec).

Then, above equations become

$$I_s=3.3 \mu A ,$$

and

$$\frac{dS}{S}=1.6 \frac{dI}{I} . \tag{4}$$

The shape of alloy junction cross section of the used transistor was observed after measurements. This junction was nearly perfect, and the surface condition of the junction seemed sufficiently good since the value of I_s at the voltage between 0.5 to 10 volt was similar to calculated value from equation (3). This suggests that the surface leakage current can be neglected, so the reverse current at 1V is only diffusion current of holes generated near the junction, and this means the noise generated in this case is originated by hole generation, i.e., $G-R$ noise, (N_r). The noise spectrum measured at 1V reversely biased voltage is shown in Fig. 1. This spectrum has no indication of $1/f$

Fig. 1. Noise spectrums of fused $p-n$ junction with various atmospheres at 1V reverse bias.

Study on the Correlation between the Noise by Hole Generation and Surface Recombination Velocity at Ge Fused Junction

By Kiichi KOMATSUBARA

Semiconductor Dep. Kobe Kogyo Corporation

(Received September 8, 1958)

The effects of surrounding atmospheres upon the saturation current, I_s , and the mean square short circuit noise current of collector junction of Ge fused $p-n-p$ transistor were measured, and the correlation between surface recombination velocity and the $G-R$ noise was studied. The junction was biased at 1V reversely when its noise was measured, and was put in vaccum or some ambient gases, O_2 , N_2 , H_2 . The values of surface recombination velocity, S , were calculated from the Websters equation of saturation current¹⁾,

$$I_s=\pi qp_0S\{2(a+\lambda_p)^2+(a^2+c^2)\} . \tag{1}$$

By differentiation, it gives²⁾

$$\frac{I_s}{dI_s} \frac{dS}{S} = - \frac{(a^2-c^2)+4a\lambda_p+2\lambda_p}{(a^2-c^2)+2a\lambda_p} , \tag{2}$$

In the present case, collector dia. $2a$ was 1.25 mm, emitter dia. $2c$ was 0.8 mm, and base width w was 0.145 mm, respectively, and the value of diffusion

noise component at 1 KC. In Table I there are presented the data of I_s and N_r measured in various atmospheres as 1V reverse voltage and center frequency of 1 K.C. and S estimated from Eq. (4). A and B are obtained from the same sample with different surface treatment to give the appreciable thickness of oxide layer before each measurement. Fig. 3 is the correlation between S and N_r/I_s and is represented by

$$N_r = C I_s S^{-L}, \tag{5}$$

where C and L are constants, and the value of L in Fig. 2 are 1~1.5. The G - R noise in germanium bar is a function of square of current flowing through crystal³⁾, but equation (5) may be able to be explained, in the case of alloy type germanium P - N junction with small value of reverse bias voltage, as it is assumed that the noise may be caused by the fluctuation of the minority carriers generated on effective area for generation, and the fluctuation by the conductivity modulation by the variation of surface potential may not be contributed to the G - R noise (at this case, $w\tau_h \ll 1$).

On RF Electrodeless Discharges in a Capillary

By Shigeo TAKEMOTO

Department of Physics, Tohoku University

Mineo KASAI

Tohoku Electric Power Company

(Received August 18, 1958)

Electrodeless discharges in high-frequency fields, from 30 Mc to 100 Mc, have been investigated. The

experimental configurations are shown in Fig. 1(a) and (b). The dumb-bell shaped discharge tubes made of hard glass and of fused silica were prepared, the spheres of about 50 mm in diameter were connected by a capillary, which is 0.1~1 mm in diameter and about 15 mm in length. The following phenomena were found at the pressure of about $10^{-2} \sim 10^{-4}$ mm Hg.

(1) When discharge tube was placed parallel to the electric field of the condenser, discharge through the capillary, with bright luminescence, was found, as shown in Phot. 1(a). If the capillary was smal-

Fig. 1.

Phot. 1.

ler than 0.1 mm in diameter, the long slender beams from the capillary extended to the ends of both spheres, and plasma density was so high that the inside of the capillary made of hard glass was damaged with many cracks in a few tenth of second. And we were able to get long term discharge only by a tube made of fused silica.

(2) When the tubes were placed parallel to the magnetic field of the condenser, only faint luminescence in the spheres and no discharge in the capillary were found, as shown in Phot. 1(b).

We believe the former type of discharge to be quite useful for light source and ion source. We are going to study the deuteron ion source of this type.

Dichroism of Color Centers in KCl Crystal

By Takehiko ISHII, Tetsuhiko TOMIKI
and Masayasu UETADepartment of Physics, The Faculty of
Science, Tohoku University,
Sendai, Japan

(Received September 5, 1958)

Many authors¹⁾ have studied the dichroic properties of color centers in alkali halide crystals by means of both absorption and emission spectra. Recently, Kuwabara and Misu²⁾ observed that the absorption coefficient of the M band measured with light polarized along the $[011]$ direction (denoted as $A_{[011]}^M$ for brevity) decreased but $A_{[0\bar{1}1]}^M$ remained constant, when the M band was bleached with light polarized along the $[011]$ direction, and pointed out the discrepancy with the earlier results by one of the present authors. We considered that this difference may have been caused by the dependence on the crystal temperature, and studied the thermal effects on the bleaching processes of M centers with polarized light. The dichroic properties of other centers were also measured.

F' centers were formed as usual by heating KCl crystal with potassium metal (M absorption was detected slightly). The crystal was irradiated with monochromatic light ($\lambda=560\text{ m}\mu$, slit width= $5\text{ m}\mu$) polarized along $[011]$ at room temperature in such a way as to produce only M centers. In this case, the dichroism in the F' and M bands were negligible. Observations were made at the temperatures 0°C , 27°C , 63°C , 83°C and 100°C for the dichroic behaviors in the F , M and R bands in the course of irradiation with M light ($\lambda=820\text{ m}\mu$, slit width= $40\text{ m}\mu$) polarized along the $[011]$ direction. Unless otherwise stated, M centers were bleached with this polarized light throughout these experiments.

The results are summarized as follows:

i) 27°C : For brevity, we define the degree of dichroism as $D=(A_{[0\bar{1}1]}-A_{[011]})/(A_{[0\bar{1}1]}+A_{[011]})$. As the bleaching of M centers proceeded, $A_{[011]}^M$ decreased, while $A_{[0\bar{1}1]}^M$ did not change as shown in Fig. 1a, and the dichroism appeared in the F' and R bands. This dichroic behavior of M centers corresponds to the results by Kuwabara et al.²⁾ In this case, $D_F < 0$, $D_R > 0$ and $D_M > 0$ were obtained. Subsequent irradiation with light ($\lambda=560\text{ m}\mu$, slit width= $5\text{ m}\mu$) polarized along the $[011]$ direction made D_F tend to zero from its negative value and made D_M and D_R tend to zero from their positive values, and then changed their signs respectively. In the case of irradiation with F' light polarized along $[0\bar{1}1]$, these reversals of signs did not occur. During the course of this F' -bleach, a

shoulder band appeared at the shorter wavelength side ($\lambda \leq 550\text{ m}\mu$) of the F' -peak. This shoulder was also observed when the crystal containing only F' centers was bleached with F' light polarized along the $[011]$ (or $[0\bar{1}1]$) direction. This fine structure of the F' band may correspond to the luminescence excitation doublet in the F' band found independently by Kuwabara and Misu³⁾.

Fig. 1. Variation of absorption coefficients of the M -band for light polarized in the $[011]$ and $[0\bar{1}1]$ directions when the M -band was bleached with light polarized in $[011]$ direction at different temperatures of 0° , 27° , 63° , and 83°C .

ii) 0°C : It was more difficult to bleach the M band at this temperature than at room temperature. When the crystal was illuminated with polarized M light, $A_{[011]}^M$ decreased and $A_{[0\bar{1}1]}^M$ increased. (cf. Fig. 1b).

iii) 63°C and 83°C : Both $A_{[011]}^M$ and $A_{[0\bar{1}1]}^M$ decreased on irradiation with polarized M light as shown in Figs. 1c and 1d. These results will correspond to our early report¹⁾. The degree of dichroism either remained nearly constant or decreased slightly when the crystal was kept in the dark for several hours at these temperatures. The absorption did not change in the wavelength region of the R band during these experiments and the shoulder just described could not be detected in the F' band.

iv) 100°C : In the similar bleaching experiment, the dichroism of the M band could not be found after the bleaching time of 5 minutes. Though it

could be produced by bleaching the F' band with polarized light, it was very small and unstable thermally. The critical temperature, at which it vanishes thermally, lies probably in the vicinity of 100°C.

These facts may probably be the evidence that the dichroic behaviors of the M band are severely affected thermally and that the dichroism is related not only with the reorientation of symmetry axes of M centers in their excited states, but also with the ionic motions. The experiment is now being extended to lower temperatures.

On the Observation of Magnetic Poles

By Eiichi GOTO

Department of Physics, University of Tokyo

(Received August 8, 1958)

Expected behaviours of magnetic poles, especially their interaction with magnetic matters are considered. The magnetic pole is supposed to be an elementary particle having magnetic true charge satisfying Dirac's quantum condition, namely 68.5 times as large as the electron charge. Magnetic poles would be attracted and trapped in ferromagnetic and paramagnetic matters. The magnetic minerals are the most promising source of magnetic poles and an efficient method for detecting the presence of even one magnetic pole among thousands of tons of magnetic minerals is proposed. This method is sensitive enough to detect such a small amount of magnetic pole as has escaped from the whole cosmic ray observations so far conducted.

§ 1. Introduction

Studies conducted so far over centuries on electromagnetism have bequeathed us the empirical law that denies the existence of magnetic true charge or magnetic poles in the nature. From the viewpoint of general theory, however, it is one of the prominent characteristics of classical electromagnetics that electricity and magnetism are perfectly symmetric with each other. The classical theories hold good without any modification even if magnetic true charge should exist. Therefore, it is a universal question anyone may raise "why only a special case where magnetic true charge does not exist actually appear in the nature, while there regions the all-embracing law applicable to more general cases where it does exist". Nevertheless, only few studies seem to have been made relating to this question and, within my knowledge, there are only those reports listed at the end of this paper.

Among them, Dirac^{1),2)} discovered the following very important fact. He gave methods for generalizing quantum electrodynamics so as to be applied to cases where a "magnetic pole" i.e. an elementary particle having magnetic true charge, exists. As a result of this generalized quantum theory, he showed that the smallest electric charge quantum, e and the smallest magnetic charge quantum, g_0 must satisfy the following quantum condition:

$$e/g_0 = 4\pi e^2/hc = 2/137 \quad (1)$$

The right side is the fine structure constant multiplied by 2 and the numerical value of g_0 (in e.m.u.) is 68.5 times greater than that of

e (in e.s.u.).

He says that an enormous energy is needed to separate magnetic poles of opposite sign, and this fact can very well explain why such particles have never been observed yet. Furthermore, formula (1) may give the only theoretical explanation so far known of the quantization of electric charge to integral multiples of e .

In regard to his theory of magnetic poles, Dirac¹⁾ himself states, "One would be surprised if Nature had made no use of it", and I also think his theory is of exceeding elegance.

In this paper, assuming the existence of magnetic poles that satisfy Dirac's quantum condition (1), behaviour of magnetic poles especially their interaction with magnetic matters will be treated. It will be shown that magnetic poles are attracted and trapped in magnetic matters. A method, utilizing this property, for detecting the existence of a magnetic pole and some other possible experiments will be discussed.

Although there are some experimental reports³⁾⁻⁶⁾ asserting the existence of magnetic poles, no one has yet received general acceptance. This seems to imply that the magnetic pole, even if it existed, might not be found much in amount. Hence, special stress will be laid on methods which will most efficiently collect magnetic poles. Possible sources of magnetic poles and experimental facts such as those obtained from cosmic ray observations will also be discussed. The most possible source of magnetic poles seems to be magnetic minerals on the earth and an effi-

ent method capable of detecting even one magnetic pole among thousands of tons of magnetic ores will be proposed.

§ 2. Behaviour of a Magnetic Pole in Magnetic Field due to various Sources

The magnetic pole treated here is assumed to be an elementary particle with magnetic charge g_0 , without electric charge and unaffected by special forces such as nuclear force, etc. The motion of such a magnetic pole will be determined by magnetic field and Lorentz force due to electric field. In regard to the sources of magnetic field, the following four kinds will be considered:

- f1) Electric Current
- f2) Permanent Magnet
- f3) Magnetic Image
- f4) Other Magnetic Poles

The magnetic field produced by electric current has potential which is multi-valued and has neither minimum point nor maximum point. Therefore, this magnetic field will be suitable for giving acceleration to a magnetic pole and will also be useful in transporting it from one place to another, but will not be suitable to confine a magnetic pole into a definite small space.

Next, the potential of magnetic field produced by a permanent magnet has maximum and minimum points in the neighbourhood of its "poles" (of the magnet). Hence, a permanent magnet will be capable to trap magnetic poles at these points. An explanation of this fundamental difference between these two kinds of magnetic fields may be given as follows. When a magnetic pole g_0 turns n times around electric current I , it obtains energy $4\pi n I g_0$ and this energy after all is supplied from the battery which supplies the current I .

On the other hand, such a phenomenon can never take place in a permanent magnet, since the magnetized state of a permanent magnet i.e. a ferromagnetic body in the state of spontaneous magnetization, corresponds to the lowest quantum energy state, and such a energy source as in the former case does not exist in the permanent magnet.

The magnetic image above mentioned means the magnetic analogy of electric field induced when an electron is in the neighbourhood of a dielectric body or a conductor. In order to

pull out an electron from a conductor, an energy called work function is needed. Similarly, a certain amount of energy will be necessary to pull out a magnetic pole from paramagnetics or ferromagnetics and it will be called the trapping energy W_m .

Now, we shall calculate the trapping energy. For the sake of simplicity, let us suppose that magnetics here is isotropic and has such a magnetizing character that the magnetisation M changes linearly from 0 to saturation value M_s when the applied field H changes from 0 to a certain value H_s . The trapping energy W_m in this case may be considered as the energy difference between two cases: one in which a magnetic pole g_0 is placed in vacuum (suffix v) and the other in which it is placed in infinitely vast magnetics (suffix f). Namely:

$$W_m = \int_{\text{volum}} dv \frac{1}{4\pi} \int_B (H_v dB_v - H_f dB_f) \quad (2.1)$$

By using polar coordinates and considering the following relations;

$$B_v = H_v = B_f = g_0/r^2 \quad (2.2)$$

$$H_f = B_f - 4\pi M_s, \quad \text{for } r < R = \sqrt{\frac{g_0}{H_s + 4\pi M_s}} \quad (2.3)$$

$$H_f = \frac{B_f H_s}{H_s + 4\pi M_s}, \quad \text{for } r > R \quad (2.4)$$

(2.1) gives the following value:

$$\begin{aligned} W_m &= \int_0^\infty r^2 dr \int_B 4\pi M dB_f = \int_R^\infty \frac{4\pi M_s B_f^2 r^2 d}{2(H_s + 4\pi M_s)} \\ &\quad + \int_0^R r^2 dr \left(\int_0^{H_s + 4\pi M_s} 4\pi M dB_f \right. \\ &\quad \left. + \int_{H_s + 4\pi M_s}^{B_f} 4\pi M_s dB_f \right) \\ &= \frac{4}{3} g_0^{3/2} (4\pi M_s)^{1/2} (1 + H_s/4\pi M_s)^{-1/2} \quad (2.5) \end{aligned}$$

Considering that the magnitude of $4\pi M_s$ is much greater than H_s for ordinary ferromagnetics, we may neglect H_s in (2.5) and obtain the following numerical value:

$$W_m = 4.966 \sqrt{4\pi M_s} \text{ eV } (4\pi M_s \text{ in gauss}) \quad (2.6)$$

Further, considering that the magnitude of $4\pi M_s$ for ordinary ferromagnetics is from 1000 to 20000 gauss, (2.6) gives the value from 160 to 700 eV.

Next, we shall consider paramagnetics, of which the relation between the magnetization M and applied field H is given in terms of

Langevin function $L(x)$ as follows:

$$M = M_s L(H\beta/kT), \quad L(x) = \coth x - 1/x, \quad M_s = N\beta, \quad (2.7)$$

where β is the magnetic dipole of a molecule, N the number of dipoles per unit volume and M_s the saturating magnetization. As the susceptibility of ordinary paramagnetics is much smaller than unity, we may replace H in (2.7) by B and (2.5) becomes

$$\begin{aligned} W_m &= \int_0^\infty r^2 dr \int_0^B 4\pi M_s L(B\beta/kT) dB \\ &= \int_0^\infty r^2 dr \int_0^{g_0} 4\pi M_s L(g\beta/r^2 kT) g/r^2 dg \\ &= \frac{2}{3} L 4\pi M_s g_0^{3/2} \sqrt{\beta/kT}, \end{aligned} \quad (2.8)$$

where

$$L = \int_0^\infty L(1/x^2) dx. \quad (2.9)^*$$

Using the values $T = 300^\circ\text{K}$ and $\beta = 1$ Bohr magneton, we obtain:

$$W_m = 1.28 \times 4\pi M_s \times 10^{-3} \text{ eV}. \quad (2.10)$$

Further, considering that the magnitude of $4\pi M_s$ for ordinary paramagnetics is from 1000 to 10000 gauss, (2.10) gives the value from 1.28 to 12.8 eV.

As this value of trapping energy and that given by (2.6) for ferromagnetics are both much greater than the thermal energy of normal temperature (about 1/40 eV), *magnetic poles will be attracted and trapped in ferromagnetics or paramagnetics and would not escape from it by thermal motion.*

As may be observed from formula (2.5), the trapping energy depends on the material constant $H_s/4\pi M_s$ only through its square root: therefore, it will be not so difficult to calculate the trapping energy for actually existing magnetic materials with fairly good accuracy.

From the fore-going studies we have learnt that any one of the magnetic matters, permanent magnet, ferromagnetics and paramagnetics has the property of attracting and trapping magnetic poles. When a magnetic body in which magnetic poles are trapped is brought in an external field which exceeds a certain critical value, the magnetic poles will be pulled out from the magnetic body. For the sake

of simplicity, we shall assume that the external field is uniform, and shall call the critical value above mentioned the critical stripping field H_{st} .

In case there is no external field, a fairly accurate value of the trapping energy was calculatable by a phenomenological treatment. On the other hand, the calculation of the critical stripping field H_{st} will be sensitive to molecular structure of the surface, so atomistic treatment will be necessary and it will be extremely difficult to calculate the accurate value of H_{st} without carrying out any experiments at all. Consequently, only rough estimations of the upper and lower bounds can be given here.

Nevertheless, it will be good enough to give quantitative basis for experiments discussed in later sections. The image field H_i attracting a magnetic pole g_0 placed at a distance R from a plane boundary of soft ferromagnetics is given, if the distance is not so small as to cause saturation, by an image $-g_0$ placed at a distance $2R$. Assuming that the permeability is much greater than unity, we obtain

$$H_i = g_0/(2R)^2, \quad \text{if } R^2 > \frac{2g_0}{4\pi M_s}. \quad (2.11)$$

Further by considering the concentrating effect of magnetic flux, we may obtain the following lower bound of H_{st} for a sphere made of soft ferromagnetics:

$$H_{st} > \frac{4\pi M_s}{16}. \quad (2.12)$$

From this formula and the facts that saturation $4\pi M_s$ of magnetite is 6000 Gauss and the value of terrestrial field is about 0.5 Gauss, we may come to the following conclusion. *Magnetic poles trapped in magnetite will not part with it by terrestrial magnetic field.*

In order to obtain an upper bound for H_{st} , the following has to be taken into consideration. An atom is trapped inside ordinary matters with trapping energy which is generally less than and at most equal to the chemical binding energy E_0 . Especially, in crystals an atom is trapped by a periodic potential, E_0 in depth. Assuming that the form of the periodic potential is sinusoidal, an external force f acting on an atom greater than $\pi E_0/l$, where l is the lattice constant, will surely separate the atom from the substance.

* The numerical value of definite integral (2.9) has been calculated by an electronic computer PC-1 and the result is: $L = 1.08778316$.

A magnetic pole trapped in a magnetic substance will also be separated if a large force as above acts on it, because even in the extreme case the magnetic pole would be separated accompanying an ordinary atom.

Here, by using the values, $E_0=2\text{ eV}$, $l=1\text{ \AA}$ and $g_0H=\pi E_0/l$, we obtain $H=30000$ oersted. This field may differ from the external field because of demagnetizing field but not much since the saturation value of any existing magnetism is less than 30000 oersted.

Unless a more accurate information on the critical stripping field H_{st} is obtained, the word, "a magnetic field greater than H_{st} ", in the later discussions must be understood as "a magnetic field as strong as possible and at least stronger than 30000 oersted".

So far, we have neglected possibility of interactions of other than electromagnetic origin. As for the behaviour of magnetic poles in ferromagnetics, however, this is not essential. As the range of such interactions is expected to be very short, if it were of repulsive nature, it would not cause any significant change in the results obtained. If it were of attractive nature, the trapping energy and other results might be affected by a small amount, since even in a extreme case in which the interaction is so strong as to form a compound particle the trapping energy (which is more than 100 eV) would only change by amount of chemical binding energy of atoms (which is about 2 eV or less).

On s4), the influence of magnetic field caused by other magnetic poles will be worth considering only if magnetic poles should be obtained in large amount. Therefore, it will not be treated here.

§ 3. Possible Sources of Magnetic Poles

The fact that no evidence of the existence of magnetic poles has yet been obtained seems to imply that even though it should exist, it would not amount to much. Possibly the reason will be sought, as Dirac says in that the magnetic charge quantum, g_0 is much greater than electric charge quantum, e . Although there is no reliable theory relating to the mass of a magnetic pole, if we assume that it has the same classical radius as an electron i.e. $r_0=e^2/mc^2=2.818\times 10^{-13}\text{ cm}$, the mass will be $(137/2)^2=4692.25$ times greater than the mass of an electron, and at least energy of 4.7

$\times 10^9\text{ eV}$ will be necessary to separate magnetic poles of opposite sign, or in other words to give rise to pair creation.

If it should be possible for us to find magnetic poles on the earth, they would be from one of the following four sources:

s1) Those existed since the formation of the earth.

s2) Those contained in the primary cosmic ray and trapped in the earth.

s3) Those created by the interaction between primary cosmic ray (nucleons) and the substance of the earth.

s4) Those created by artificial accelerators.

The first three relate to possible natural sources. Through the studies in § 2, magnetic poles should be attracted and trapped in paramagnetic or ferromagnetic matters, and it is also known that such magnetic matters are very widely distributed among earth crust. Hence, natural magnetic poles should be concentrated on magnetic minerals in earth crust. Specially, if a state near thermal equilibrium is realized, magnetic poles will be concentrated in the largest rate on ferromagnetic minerals such as magnetite and magnetite sand.

In regard to s1), as the inside of the earth is of exceedingly high temperature, ferromagnetics will not be present and thermal agitation will be fairly large; therefore, the magnetic poles will move by force of terrestrial magnetism and will finally be attracted and trapped in magnetic minerals distributed among earth crust.

As for magnetic poles, s2) and s3), originated from cosmic ray, the large ionization loss of magnetic poles, referred to later, must be taken into consideration. The energy of magnetic poles will be lost at high altitude because of ionization loss and other losses in the air, and those which receive downward force from terrestrial field will reach the surface of the earth and will finally be trapped in magnetic minerals. In the northern and southern hemisphere, the polarity of these magnetic poles will be opposite with each other.

On s2) and s3), the integration effect on time i.e. time-elapse of at least 10^8 years since the formation of earth crust, will be a very important factor.

If we think of the cosmic ray as a source for magnetic poles, a question may arise as

to its relation to the fact that no trace of a magnetic pole has yet been found in any of the cosmic ray observations so far conducted. The total integration of the cosmic ray observations will surely not exceed the value: a detector of 100 m^2 being operated for 100 years. Though this value seems to be an extreme over-estimation, if it is taken into consideration that magnetic poles have never been searched purposely, the value is equal to that which came into only 1 cm^2 in 10^8 years. In other words, the total sum of the cosmic ray observations so far conducted corresponds at most only to the examination of magnetic minerals under 1 cm^2 of the surface of the earth. Consequently, the failure of direct observations made on cosmic ray to find magnetic poles would be no deterrent of starting the examination of magnetic minerals.

Next, as to the accelerator, the largest ones at present are the Phasotron and the Bevatron and generally these produce 10^{10} eV protons at the rate 10^9 particles/sec. Consequently, by operating these continuously for 1 year, we may obtain 3×10^{16} particles. As the intensity of primary cosmic ray having energy greater than 10^{10} eV is about $10^{-1} \text{ particles sec}^{-1} \text{ cm}^{-2} \text{ sterad}^{-1}$, the above value corresponds to the cosmic ray which came into only 15 cm^2 in 10^8 years. Besides, energy of 10^{10} eV does not seem enough to cause pair creation of magnetic poles. If this is the case, we will come to the following conclusion. *In order to find a magnetic pole, the only way possible at present to do is to examine magnetic minerals in the earth crust.*

§ 4. A Method for Collecting and Detecting Magnetic Poles

Magnetic poles will be separated from magnetic minerals by applying a external magnetic field much stronger than the critical stripping field H_{st} discussed in § 2. The re-collection of the magnetic poles separated in this way will be accomplished by placing a ferromagnetic plate (this will be called the "target") at a position where the magnetic field becomes weaker than H_{st} . In this operation, magnetic poles of opposite polarity will fly out to opposite directions so that it will be possible to collect them on separate targets.

By this method, it will be possible to transfer even one magnetic pole among thousands

of tons of magnetic minerals to a target of relatively small size, say 1 kg in weight. By repeating similar operations in each of which the magnetic pole is separated from a target and re-collected into another smaller target, it will be possible to transfer the magnetic pole into a magnetic body of very small size.

One method of detecting the existence of a magnetic poles is to observe the movement of a small magnetic particle which is supposed to have trapped a magnetic pole. In an external magnetic field less than the critical stripping field H_{st} , the particle will show behaviour as if it were only possible to be explained by the fact that the particle has magnetic true charge. For example, if an iron sphere, in which a magnetic pole g_0 is trapped and having diameter less than $2/100 \text{ mm}$, is placed in a uniform vertical magnetic field of 1000 oersted strong, the sphere will move upwards counteracting gravity. Considering (2.12), the field of 1000 oersted will be less than H_{st} and the observation of the motion of a sphere, $2/100 \text{ mm}$ in size, will be made very easily.

It seems that Ehrenhaft⁽⁴⁾⁻⁽⁶⁾ and others might have observed such a phenomenon as above.

In order to transfer a magnetic pole trapped in a target to such a particle as used in the above experiment, iron powder, i.e. ensemble of such particles, may well be used as the final target. The particular one particle having trapped a magnetic pole, may be separated from other particles by means of a magnetic field.

It will also be possible to measure the value of the magnetic charge quantum, g_0 by observing the motion of the above mentioned particle in viscous fluid and this will be almost the same as Millikan's oil drop experiment.

§ 5. Discussion and Remarks

The experiments in regard to the detection of magnetic poles discussed in § 4 were static. These static experiments seem to be the most effective and unfailing method of collecting and detecting magnetic poles existing only in very small numbers. If once the existence of a magnetic pole has been confirmed in this way, it will be quite easy to carry out various kinds of dynamic experiments by accelerating the magnetic pole. It is easy to ac-

celerate magnetic poles up to high energy. For 1 e.s.u. of electric field is 300 volt/cm and magnetic charge quantum is 68.5 times as large as the electron charge, 1 orsted cm of magnetic field will accelerate a magnetic pole, g_0 up to $300 \times 68.5 = 2.055 \times 10^4$ eV. Here, take a magnetic field, 10000 orsted strong and 100 cm long; it will provide an accelerator of 2×10^{10} eV, and further, it will be not very difficult to obtain accelerators 100 or even 1000 times stronger. In order to inject magnetic poles into such accelerators, it is only to apply a impulsive field sufficiently greater than the critical stripping field H_{st} on the magnetic body in which it has been confirmed by static experiments that magnetic poles have been trapped. The great value of ionizing power of magnetic poles has been already pointed out and calculated by Dirac²⁾, Yazaki and Miyatake⁷⁾. Especially, Dirac states, "they would appear as heavily ionizing particles and would be distinguishable from ordinary charged particle by the property that the ionization they produce would not increase towards the end of their range, but remain roughly constant". Therefore, it would be quite easy to observe the traces of magnetic poles by cloud chambers and the like. From these dynamic experiments, we shall be able to study interactions between magnetic poles and other elementary particles.

Particularly, the charge to mass ratio, g_0/m will be measured through the speed of magnetic poles of which the energy is known.

As a magnetic pole never vanishes unless it should meet another magnetic pole of opposite polarity, the magnetic pole used in a dynamic experiment can always be trapped inside a ferromagnetic shield surrounding the whole apparatus of the experiment, and afterwards it may be re-collected by the method discribed in § 4. Therefore, even one magnetic pole should be found in the whole world, then the one could be used repeatedly for almost all kinds of experiments except those relating to annihilation.

In order to study the interaction between two magnetic poles of opposite polarity, unless we could obtain magnetic poles in large quantity, there will be no other way but the static

method. When two small magnetic bodies (spheres of diameter 1/100 mm, for example) which have each trapped a magnetic pole of opposite polarity are put together, reaction will occur between magnetic poles attracting each other. From the energy of γ ray produced in this reaction, we shall be able to know whether these two have caused annihilation as between an electron and a positron or produced an atom as between an electron and a proton.

§ 6. Conclusion

We have found out that if a magnetic pole should exist it should be attracted and trapped by magnetic matters. From this property, it is presumed that natural magnetic poles, which have either been existing since the formation of the earth or originated from cosmic ray, are concentrated on magnetic minerals in the earth crust and also it has become known that there is an efficient and unfailing method of collecting and detecting such natural magnetic poles. Besides, we have reached the conclusion that even though direct observations of cosmic ray or experiments relating to artificial accelerators may fail to find magnetic poles, there is fairly large probability of discovering them among magnetic minerals because of integration effect lasting at least for 10^8 years. Under these circumstances, I believe it is at least worth while to try experiments with regard to magnetic minerals and hope that they will be started at an earliest opportunity.

On closing the author wishes to express his sincere thanks to professor H. Takahasi for his encouragement and discussion.

Gamma Ray Spectroscopy of Mn⁵⁴

By Toshio KATOH, Masao NOZAWA, Yasukazu YOSHIZAWA

Department of Physics, Faculty of Science, Osaka University, Osaka

and Yujiro KOH

Faculty of Science and Engineering, Osaka City University, Osaka

(Received August 20, 1958)

Internal conversion electrons of 0.84 Mev gamma ray were measured by a two-directional focusing beta-ray spectrometer, and it was determined that $E_\gamma = 837.9 \pm 0.3$ kev and $K/L + M = 8.5 \pm 0.7$. Weak gamma rays were searched, using scintillation counters, but no gamma ray was observed.

§ 1. Introduction

It has been well known that Mn⁵⁴, 290 days, decays to the first excited state of Cr⁵⁴, through the electron capture. Neither positive nor negative beta ray was found¹⁾. The 0.84 Mev gamma transition from the first excited state is E2 transition and the spin and parity of this level are $2 + ^{2), 3)}$. The internal conversion coefficient or K/L has not been reported.

The internal conversion electrons of this gamma ray were measured using the two-directional focusing beta-ray spectrometer with the mean radius, $\rho = 40$ cm⁴⁾, and the gamma ray energy and $K/L + M$ were determined. As the gamma ray of Mn⁵⁴ was precisely measured and moreover it is single gamma ray, Mn⁵⁴ should be used as a good standard gamma emitter, especially, for the calibration of the scintillation spectrometer.

In general the second excited state of even-even nucleus is expected to be about twice higher than the first excited state. It was measured that the energy 0.528 Mev⁵⁾ is emitted in the electron capture. Hence the decay energy between the ground states of Mn⁵⁴ and Cr⁵⁴ is 1.37 Mev, which is expected to be lower than the second excited state. Nevertheless in order to investigate whether the second excited state is lower than the ground state of Mn⁵⁴ or not, weak gamma rays were searched for.

§ 2. Source Preparation

Mn⁵⁴ was produced by bombarding the internal target of Cr with deuteron beam accelerated by the Osaka 11.4 Mev cyclotron. Cr was electroplated on copper sheet. After bombarding Mn was oxidized by Br₂ and

separated by the radiocolloid method⁶⁾. The carrier free source for spectrometer was deposited on 0.8 mg/cm² mylar film covered with thin aluminum layer.

§ 3. Gamma Ray Energy and $K/L + M$

The internal conversion lines of the 0.84 Mev gamma ray were measured. In the case of the precise energy measurement, the gamma ray of Co⁶⁰ and Cs¹³⁷ were used for the standard gamma rays and the gamma rays of Mn⁵² were also used for the substandards⁷⁾. The results are shown in Table I. The resolution of the spectrometer was 0.7 percent in this measurement.

Table I. The energy of gamma ray of Mn⁵⁴

E_γ (kev)	Method	Reference
833 $\pm$ 15	Lens spectrometer	a)
825 $\pm$ 20		b)
840 $\pm$ 7	Scintillation Spectrometer	c)

b) G. H. Stafford and L. H. Stein, Nature 172 (1954) 1103.		
c) Maeder, Wapstra, Nijh and Ornstein, Physica 20 (1954) 521.		

In our spectrometer L and M conversion lines cannot be separated, but K and $L + M$ lines are slightly splitted, though the resolution of 0.7 percent is larger than usual. $K/L + M$ was determined to be 8.5 ± 0.7 . This value is larger than the theoretical value⁸⁾ for E2 transition beyond the experimental error, as shown in Table II. The screening effect are neglected in Rose's theoretical values for

M-shell. This effect can decrease the *M*-shell value by a factor 0.6⁹⁾, and the theoretical value becomes in agreement with experimental one.

Table II. Theoretical and experimental Values of $K/L+M$

Experimental	Theoretical			
	<i>E</i> 1	<i>E</i> 2	<i>M</i> 1	<i>M</i> 2
8.5±0.7	8.1	7.7	8.0	7.8

§ 4. Search of Weak Gamma Ray

Only 0.84 Mev gamma ray has been reported in Mn⁶⁴ decay. If the second excited state of Cr⁶⁴ is lower than the ground state of Mn⁶⁴ and has the spin and parity of 2+, a weak high energy gamma ray may be observed. If the spin and parity of such a state are 2+ or 4+, the coincidence measurement with the 0.84 Mev gamma ray can show the existence of a weak cascade gamma ray. In order to research such unknown weak gamma rays, two scintillation counters of 1½ inch NaI and 20 channel pulse height analyzer were used for the single as well as the coincidence counting method. Sources were MnCl₂ solution of about 100, 10 and 1 μC.

However, no gamma ray was observed, and upper limit of gamma rays were determined to be about 10⁻⁴ per one decay for the high

energy gamma ray in the single count measurement and to be about 10⁻³ for low energy gamma ray in the coincidence measurement.

§ 5. Acknowledgement

The authors wish to express their thanks to Prof. S. Kikuchi, Prof. T. Wakatuki, Prof. J. Itoh and the cyclotron group for their interest and many helps. They are indebted to Prof. K. Otozai, Mr. S. Kume, Mr. S. Iwata, Mr. Y. Yamamoto and Mr. I. Fujisawa for the chemical separation, and also to Dr. M. E. Rose for the internal conversion coefficients.

Grain Boundary-Hardening due to Piled-up Dislocations

By Jin-ichi TAKAMURA and Sei MIURA

Department of Metallurgy, Kyoto University, Kyoto

(Received August 28, 1958)

The grain boundary in deformed bicrystals of α -brass has the hardening layer of 50~100 microns in thickness. Evidences for the assumption that the hardening is attributable to the dislocations piled up against the grain boundary were provided by the fact that the amount of hardening could be reduced by the application of reversed stress, and also by the analysis of the hardness distribution which showed the amount of hardening to be approximately proportional to the density of piled-up dislocations.

§ 1. Introduction

A linear array of like dislocations piled up against a barrier has been treated in detail by Eshelby, Frank and Nabarro¹⁾. And it has been suggested by Mott²⁾ that the strains around piled-up groups of dislocations are responsible for the intense work-hardening of metals. Such a barrier may be, for instance, a grain boundary; it would be expected to be more hardened at the grain boundary than in the grain of deformed polycrystals.

Evidences for piled-up dislocations have been obtained by producing etch pits at the sites of dislocations in α -brass by Jacquet³⁾, Bilby and Entwisle⁴⁾, and Sun and Wilsdorf⁵⁾, and also in zinc crystals by Gilman⁶⁾. The present work was undertaken for the purpose of providing a clearer picture of the grain boundary-hardening caused by the piling-up of dislocations. α -brass was chosen for the specimen and the hardening was measured by a microhardness tester.

§ 2. Experimental Details

Bicrystal specimens of 70-30 brass, 8 mm square in cross section, were grown by the Bridgman method in split molds of graphite. Test specimens, originally polished mechanically, were electropolished in a solution of phosphoric acid. Specimens were next fully annealed in Ar at 800°C. After the deformation by Amsler testing machine, specimens were again carefully abraded through emery paper to flatten the surface and then electropolished in order to eliminate completely the abrasion effect. This technique was necessary for minimizing the amount of dispersion of microhardness measurements. The microhardness testing was carried out with a load of 25 gr.

Fig. 1. Relative position of the grain boundary with respect to the slip direction in bicrystal specimen No. 2.

Fig. 2. The observation surface of bicrystal specimen No. 2 as extended by 9.3%. $\times 3$

Fig. 1 shows the relative orientation of a bicrystal specimen No. 2. This can be seen also in Fig. 2. The vertical direction in the figures is the specimen axis and it is illustrated in the stereographic projection of Fig. 3.

Let φ be the relative angle of the mean direction of the curved grain boundary with respect to the slip direction on the active slip plane of crystal A, then $\varphi \simeq 80^\circ$ as understood from Fig. 1. This means that dislocations held up against the grain boundary have almost pure edge component. Microhardness measurements were made on crystal A as shown in Fig. 4.

Fig. 3. Specimen axes of bicrystals A and B illustrated in Fig. 1. Here, θ is the angle between the specimen axis and the normal to the slip plane, λ the angle between the axis and the slip direction, η the angle between the slip direction and the direction of maximum slope on the slip plane.

Fig. 4. The measurement of microhardness in the grain boundary region of specimen No. 2 extended by 9.3%. $\times 290$

§ 3. Results

It can be seen in Figs. 4 and 5(a) that the grain boundary region of deformed specimens is much hardened; the thickness of the hardening layer in most specimens used in this experiment ranges from 50 to 100 microns.

The application of reversed stress, for instance, the compression subsequent to the extension alters the distribution of hardness; the amount of hardening at the grain boundary much decreased and the hardness in the

center of grain, on the other hand, showed slight increase, as clearly shown in Fig. 5 (1) and also in the composite diagram of Fig. (c).

Fig. 5. The distribution of hardness in crystal A of specimen No. 2. The lowest diagram shows the difference in the distribution between diagrams (a) and (b).

§ 4. Discussion of Results

It is first necessary to examine whether the hardening at a grain boundary is attributable to the piling-up of dislocations. Evidence in favor of it was provided by the fact that the application of reversed stress had changed the distribution of hardness in the grain boundary region, as indicated in Fig. 5(c). This observation strongly supports the supposition that the dislocations piled up against the grain boundary have jumped back towards the center of grain and dispersed there rather uniformly. It should be noticed that the observation is closely connected with the Bauschinger effect.

Now we shall consider the distribution curve of hardness given in Fig. 5(a). Assuming that the amount of increase in hardness, ΔH , is proportional to the density of piled-up dislocations, we have

$$\Delta H = k \frac{dn}{dx} \quad (1)$$

Here k is the constant and n is the number of piled-up dislocations lying between the grain boundary and a point at the distance x from it, which is given under the acting stress σ by the following equation¹⁾

$$n = cx^{1/2}, \quad (2)$$

where

$$c = (2/\pi)(2N\sigma/A)^{1/2},$$

$$A = \mu b(1 - \nu \cos^2 \varphi) / 2\pi(1 - \nu),$$

and N is the total number of piled-up dislocations, μ the shear modulus, ν the Poisson's ratio and b the strength of dislocation. Eliminating n between (1) and (2), we obtain

$$H = (kc/2)x^{-1/2} + H_0, \quad (3)$$

where H_0 is the hardness at a position far away from the grain boundary. Thus if, as in Fig. 6, we plot H against $x^{-1/2}$, we should

Fig. 6. Microhardness data plotted as a function of $x^{-1/2}$. Here x is the distance from the grain boundary.

get points which cluster around a line of slope $kc/2$ with an intercept H_0 on the hardness axis. The figure shows that this is the case, although some rearrangement of the piled-up dislocations should have taken place during the relaxation of the load after straining; it can be said that the amount of hardening at the grain boundary region is approximately proportional to the density of dislocations and

hence a large part of the grain boundary-hardening is ascribed to the piled-up dislocations.

§ 5. Summary

A study on the grain boundary-hardening in deformed bicrystals of α -brass was carried out by microhardness testing. The results obtained are as follows. The grain boundary of deformed bicrystals has the hardening layer of 50~100 microns in thickness. A large part of the grain boundary-hardening is ascribed to the piling-up of dislocations.

Evidence in favor of this conclusion was provided by the observation that the application of reversed stress had altered the distribution of hardness as shown in Fig. 5. It should be noticed that the observation is closely connected with the Bauschinger effect. Another proof was given by the analysis of the hardness distribution, which showed the amount of hardening to be approximately proportional to the density of the dislocations piled-up against the grain boundary.

On the V-centers in KBr Crystals

By Yoshio NAKAI

Yoshida College, University of Kyoto

(Received September 11, 1958)

The natures of V bands in the additively colored crystals of KBr has been investigated. Mollwo's results were confirmed and extended. A new technique of additive coloring was devised to produce a high concentration of V centers in the crystal of KBr. By using this method, the degree of coloration could be increased by about ten times of that reported by Mollwo. Besides the well-known V_2 and V_3 bands, another band of V-type was observed below $210\text{ m}\mu$.

It was found to be possible to color electrolytically the crystal of KBr revealing the same absorption spectrum as that of additively colored crystals. Evidently, this confirms that these absorption bands are produced as the result of the combination of positive holes and positive ion vacancies. Discussions were made in comparison with the results obtained for KBr colored with X-rays.

§ 1. Introduction

It is possible to color certain of the alkali halides by heating them in the proper halogen vapor. This was done by Mollwo for $KI^{(1,2)}$ and $KBr^{(2)}$. Absorption was produced in the ultraviolet region of the spectrum. The absorption band did not have a simple bell-shaped form as seen in the F-band but seemed to consist of two or more overlapping bands. This group of bands has been named the V-band by Seitz³⁾.

Similar absorption is produced in the ultraviolet region when crystals of KCl and KBr are exposed to X-rays. Recently, various experiments on the V-bands have been carried out mainly on the crystals colored with X-rays.

The V center problems are reviewed systematically and discussed in great detail by Seitz⁴⁾. He proposed various models for V centers, V_1 , V_2 , V_3 , V_4 etc., which show definite absorption bands in the optical spectrum of the colored crystals under a certain condition specified for each case. Mollwo's result²⁾ plays an important role in his discussions about V_2 and V_3 centers. The main band, $365\text{ m}\mu$ in KI and $265\text{ m}\mu$ in KBr, was named V_2 band and the shoulder, $275\text{ m}\mu$ in KI and $240\text{ m}\mu$ in KBr, on the shorter wavelength side of the main band was named V_3 band. Considering the natures of these bands with various informations obtained from the studies on the crystals colored with X-rays, he proposed that the V_2 center consists of two

positive ion vacancies and two positive holes trapped by them, while the V_3 center consists of two positive ion vacancies and one positive hole.

Unfortunately, however, the correspondence is rather poor between the spectra of V-band obtained by the above-mentioned two methods of coloration for certain kind of salt. This state of affairs is quite different from the case of F-band and seems to prevent more or less the development of studies on the V-center problems. In KCl and NaCl, the V-bands produced by X-ray coloring have been studied in detail^(5,6) but, so far as the writer is aware of, the additive coloration has not been found to be possible for these crystals. On the other hand, the additive coloration is possible for $KI^{(2,7)}$ but no definite correspondence seems to exist between the results of additive coloration and the results of the study carried out by Hersh⁸⁾ on this crystal exposed to X-rays. The state of things is not so hopeless for KBr, because both additive²⁾ and X-ray^{(5), (6), (8), (9)} coloration have been found to produce the similar absorption at least in the short wavelength region of the spectra. However, informations about the V-bands in the additively colored crystals are available only from the Mollwo's work which was carried out about twenty years ago.

Hence it seems important to investigate in the light of recent informations the natures of V-band in additively colored crystals. The present study is concerned with some proper-

ties of the V-bands in the additively colored crystals of KBr.

§ 2. Experimental Methods

i) General

Crystals of KBr were grown in our laboratory by using the Kyropoulos method. Greater part of the experiments was repeated also on the crystal which was available through the kindness of Professor Maurer of the University of Illinois. No significant difference was found between the experimental results obtained for both crystals.

The optical measurements were made using a Beckman-DU or Shimadzu-QB spectrometer both at room and liquid air temperatures, the optical absorption of the crystal having been obtained in terms of $\log(I_0/I)$, where I and I_0 are the intensities of light with and without the crystal sample in the light path respectively. Hence it is necessary to subtract the absorption of uncolored crystal having the same thickness as that of colored specimen in order to obtain the absorption constant. A mercury arc lamp of AH-6 type with a quartz envelope was used to illuminate the crystal. Since this mercury lamp is of super high-pressure type, the relative intensity in the ultraviolet region is rather low. However the very high total brightness of this lamp overcomes sufficiently such a drawback.

ii) Technique of additive coloring

Fig. 1 shows the cross-sectional view of the

vessel used in the additive coloration. The crystals of KBr were sealed in the evacuated quartz tube with a certain amount of bromine. This tube was inserted into the stainless steel container with an adequate quantity of water, and this container was then packed tightly using a copper ring as a gasket material.

Use of water keeps the quartz tube from breaking due to a rise of bromine pressure at high temperature. Since the vapor pressure of water increases with temperature very much alike that of bromine, both inside and outside of quartz tube suffer nearly the same pressure in raising the temperature. Van der Waals' equation was used to determine the adequate quantity of water producing the best fit of pressure for the quantity of bromine sealed in the quartz tube.

The whole vessel was heated at 600°C for about three hours, and then quenched to room temperature within ten minutes by dropping it into a water-tank. It was necessary to store colored crystals below -40°C in order to prevent its thermal bleaching.

Usually, colorations were made under 50~100 atmospheric pressure of bromine. This method makes it possible to color the crystal about ten times as much as that reported previously²⁾.

Unfortunately, degree of coloration was never reproducible; in other words, absorption constants of the colored crystals varied from case to case in spite of great care taken for the crystal temperature and the density of bromine surrounding the crystal. Therefore, no definite relation could be found between the solubility of Br_2 in KBr and the concentration of Br_2 in the vapor.

§ 3. Absorption Spectra

The typical absorption spectrum of the additively colored crystal of KBr is shown in Fig. 2, curve a. Coloration was made at 630°C in the bromine gas of 50 atmospheric pressure. For comparison, Mollwo's result is also shown by curve b for which the ordinate scale is given on the right-hand side of the figure. Curve c shows the absorption of uncolored crystal used in the present experiment using air as blank. All measurements were made at room temperature.

The main band having its maximum at 265 $\text{m}\mu$ coincides exactly with the peak obtained by Mollwo, and, as described above, this is

Fig. 1. Cross-sectional view of the vessel used in the additive coloration of KBr.

named the V_2 band in recent literatures. A sharp rise occurs below $210\text{ m}\mu$ in curve a, but not in curve b. Since this region is located near the short wavelength limit of the spectrometer used, the precise determination of peak wavelength was impossible. The hump occurring at $410\text{ m}\mu$ in curve b does not appear at all in curve a, and the shoulder at $240\text{ m}\mu$ in curve b, named recently the V_3 band, is not so well defined in curve a. As will be described later, part of these differences can be ascribed to the thermal instability of the main band (V_2 band).

Fig. 2. Absorption spectra of additively colored crystal of KBr measured at room temperature. Curve a: colored at 630°C in Br_2 of 50 atm. pressure (left-hand scale); curve b: after Mollwo (right-hand scale); curve c: uncolored crystal used in the present study (left-hand scale. Absorption is plotted *versus* air.).

It is worth mentioning that the exactly same spectrum as that shown by curve a in Fig. 2 was obtained in the crystal colored electrolytically by using a pointed anode. As reported previously⁷⁾, when a certain amount of current is passed in the blank crystal of KI from a sharp anode at high temperature, the crystal is colored* and shows the same absorption

* Attempt to measure the drift mobility of V -centers was made by Mollwo by applying a uniform static field at high temperature to the additively colored crystal of KI, but he did not try to color the crystal by using a sharp anode.

spectrum as that of additively colored crystals of KI. Similar facts were confirmed also for KBr as shown in Fig. 3. The measurements were made both at room and liquid air temperatures.

By lowering the measuring temperature the width of the main band decreased as expected. However the temperature shift of the peak wavelength was not so large as that of the F band. Indications of some component bands are seen near $240\text{ m}\mu$ and $300\text{ m}\mu$ in the low temperature spectrum. Therefore, the main band observed at room temperature can never be recognized as a purely single band.

Fig. 3. Absorption spectra of the electrolytically colored crystals of KBr. Curve a: measured at room temperature; curve b: measured at liquid air temperature.

§ 4. Thermal Behavior

It was found that the V_2 band is stable only when the colored crystal is stored below -40°C . At room temperature, the V_2 band decreases gradually and the enhancement of absorption occurs near $240\text{ m}\mu$ and $300\text{ m}\mu$. Fig. 4 shows the effects of aging the colored crystal at room temperature. Curve a shows the absorption immediately after the additive coloration. As long as the temperature of the colored crystal is kept below -40°C by using dry ice as coolant, absorption curve does not change at all. However aging for 24 hours at room temperature produces a slight change as shown by curve b. Curves c and d show the spectra after aging for 18 days and 60

days at room temperature, respectively. Needless to say, the crystals were kept in dark to exclude the effect of light.

The rate of this process is considerably increased by heating the colored crystal at higher temperatures instead of aging it at room temperature. For example, by heating at 200°C, the final state was established in three hours having nearly the same absorption as in the case of bleaching at room temperature.

Fig. 4. Thermal destruction of V band in KBr at room temperature. Absorption was measured at room temperature. Curve a: initial state, immediately after the additive coloration; curve b: after aging for 24 hours; curve c: after 18 days; curve d: after two months; curve e: restoration of the original bands after heating at 550°C for 30 minutes.

It is interesting enough to note that, as shown in Fig. 4 curve e, the original bands are nearly reproduced by heating these crystals above 550°C for 30 minutes and quenching from that temperature. In addition, no difference was found between the properties of the recovered crystals and the freshly colored crystals. This means that the bleached crystal can always be restored by this method, that is, storing the colored crystal below -40°C is not required for the most part of the present study.

§ 5. Optical Bleaching

It is possible to bleach the V_2 band by illuminating the colored crystal at room temperature with light absorbed in this band. Fig. 5 shows the light bleaching of V band irradiated at room temperature. A light from AH-6 mercury lamp with the appropriate filter was used to illuminate the crystal. Main band at 265 $m\mu$ was bleached considerably and the enhancement of absorption occurred near 240 and 300 $m\mu$. General view of the spectrum was similar to that of thermal bleaching.

Fig. 5. Light bleaching of V_2 band in KBr by illuminating with the mercury lamp at room temperature. Absorption was measured at room temperature. Curve a: initial state, additively colored; curve b: after having irradiated for 1/2 hours; curve c: after having irradiated for further 12 hours; curve d: after having irradiated for further 12 hours.

However, enhancement in the short wavelength side of the main band seems relatively larger than in the case of thermal destruction. This difference makes its appearance in Fig. 5 (curves c and d) as a gradual shift of the main peak toward the short wavelength side in the course of the optical bleaching.

Fig. 6 shows the absorption after irradiating for four hours both at liquid air and at room temperature, all absorption measurements having been made at liquid air temperature. Irradiation at liquid air temperature

was made because it was expected that, at low temperatures, the V_1 band might be formed as the result of dissociation of the V_2 centers by illuminating them with the light in the V_2 band. However, no significant change was produced by irradiating at liquid air temperature (from curve a to curve b) in comparison with the case of irradiation at room temperature (from curve b to curves c and d).

Fig. 6. Light bleaching of V_2 band in KBr by illuminating with the mercury lamp. Absorption was measured at liquid air temperature. Curve a: initial state, electrolytically colored; curve b: after having irradiated at liquid air temperature for 4 hours; curve c: after having irradiated at room temperature for 4 hours; curve d: after having irradiated at room temperature for further 4 hours.

Similar experiment was made by using a monochromatic light (Hg 265 $m\mu$ line) to bleach the V_2 band in order to obtain the efficiency of this optical bleaching processes measured in terms of the number of V_2 -centers destroyed per absorbed quantum of light. This quantity will be called the quantum yield for optical bleaching, and will be designated by η .

In practice, the number of V_2 -centers destroyed was obtained from the change of absorption constant at 265 $m\mu$ using the formula derived by Smakula¹⁰ in which the oscillator strength of this band was taken as unity. The calibrated thermocouple was used to know the number of light quanta absorbed, the readings of which were made when the height of the V_2 -band has decreased to about 95 per cent of its initial value.

Thus it was found that the value of η at room temperature is 0.042, and η at liquid air temperature is less than one hundredth of this value. Qualitatively, it is obvious from Fig. 5 that η will decrease with increasing time, thus reaching nearly zero after the prolonged period of irradiation. Therefore the value of η obtained in this experiment is the one averaged over the initial period of illumination.

If the optical bleaching of the V_2 -band is due to the release of holes from their traps, the bleaching process should be accompanied by a photocurrent. Then the yield for the production of free hole, η' , may be assumed as being equal to the value of η obtained in the experiment of light bleaching.

A current larger than 10^{-12} amperes could be expected by using a usual formula for the photocurrent, if we assume that η' is equal to the quantum yield for optical bleaching at room temperature, 0.042, and that the mean range of free hole, ω_0 , is equal to the value obtained by Dutton and Maurer¹¹ in the crystal of KBr irradiated with X-rays at low temperatures*. But, contrary to these expectations, such a magnitude of photocurrent was never observed; it was not possible to obtain any signal which exceeds the noise level (0.7×10^{-14} amperes) of the amplifier used in the present experiment. This means that the assumptions made above are not adequate. In practice, it seems unlikely that the magnitude of ω_0 in this case is far less than that of Dutton and Maurer, even if we take into consideration that the temperature and the density of traps in colored crystals are appreciably different for both cases. Accordingly, it will be supposed that η' must be much smaller than

* Photocurrent is given by the expression:

$$I = N\eta'e\omega_0 E/d,$$

where N is the number of light quanta absorbed per second, η' the fraction of these which actually release holes, ω_0 the mean range of free hole in unit field strength, E the electric field, and d the distance between electrodes.

N was larger than 10^{16} quanta/sec when the filtered light from AH-6 lamp was focused with a usual quartz lens. It was assumed, as described above, that $\eta' = \eta = 0.042$ and $\omega_0 = 3 \times 10^{-11}$ cm²/volt. Electric field of 2000 volt/cm was used and d was 0.3 cm. Then we have

$$I \geq 1.3 \times 10^{-12} \text{ amperes.}$$

7. This means that either the tunneling of holes from the excited state of the V_2 center or the photo-dissociation processes will be rather predominant in bleaching the V_2 band. Further details will be discussed later.

§ 6. Electrolytic Bleaching

It was found by Mollwo²⁾ that when an electrostatic field is applied to the colored crystal at high temperature, the flow of currents is observed in excess of the purely ionic current which will be obtained in uncolored crystal at the same temperature. The magnitude of this current decreases with time, reaching finally a steady ionic current. Mollwo

used this method to determine the number of V centers contained in the crystals of KI and of KBr colored additively.

In the present study, attention was paid on the variation of absorption spectrum in the course of these processes. The results obtained are shown in Figs. 7-9. In Fig. 7 is shown the decrease of the excess currents with increasing time, and in Fig. 8 the absorption spectra before and after the application of the electric field to the colored crystal at 570°C. It should be noted that 265 m μ and <210 m μ bands have disappeared in this case and the resultant spectrum differs little from that of the original blank crystal.

Fig. 7. Current versus time curve. A potential of 400 volts was applied at 570°C for an electrolytically colored crystal of KBr.

Fig. 8. Electrolytical bleaching of V bands in KBr at 570°C. Absorption was measured at room temperature. Curve a: original uncolored crystal; curve b: after colored electrolytically; curve c: after bleached electrolytically.

Fig. 9. Variation of V bands in KBr with increasing time of current flow. Absorption measurements were made for the narrow portions of the crystal sample near cathode (Fig. 9A), and near anode (Fig. 9B). In both figures, curve a: initial state, colored electrolytically; curve b: after a flow of currents by applying 135 volts for 90 seconds at 593°C; curve c: after a further flow of currents by applying 135 volts for 120 seconds at 610°C.

Further, it was found that the destruction of V band begins in the portion of the colored crystal near anode as shown in Fig. 9A and B. This experiment was done by comparing the spectra obtained from two narrow parts of the same specimen, the one near cathode and the other near anode, at various early stages of current flow. Fig. 9A shows the spectra of the part near cathode, and Fig. 9B those near anode. In both figures, curve a shows the spectrum before the application of the electric field and curves b and c show those after the flow of current produced by applying 135 volt for 90 sec at 593°C and for 120 sec at 610°C, respectively. Despite of curves a and b being of nearly equal height in the part near cathode (Fig. 9A), the height

of curve b is about one half of that of curve a in the part near anode (Fig. 9B). In addition, comparison of curves c in both parts shows that when the absorption in the cathode side decreases to about one half of its initial value, the absorption is no longer seen in the anode side.

Finally, it is to be noted that the degree of destruction is nearly equal for both 265 $m\mu$ and 210 $m\mu$ bands, namely, the relative intensity of these bands is not altered in the course of these processes. This fact suggests that color centers responsible for these two bands can drift toward the cathode, so that positive holes play an important role in the species giving rise to these bands.

§ 7. Discussions

The results of the present experimental investigations are summarized in the following:

1. The same absorption spectrum was obtained for the KBr crystals colored either additively or electrolytically.

2. Two strong bands were produced at 265 $m\mu$ and below 210 $m\mu$ immediately after the coloration was made (Fig. 2).

3. Indications of two subsidiary bands appeared at about 240 $m\mu$ and 300 $m\mu$ when measured at low temperature (Fig. 3).

4. When the colored crystal of KBr is kept or irradiated with a light absorbed in the 265 $m\mu$ band at room temperature, this band is lowered and the 240 $m\mu$ and 300 $m\mu$ bands are enhanced without significant change in the range below 210 $m\mu$ (Figs. 4-6).

5. Release of free holes was not observed upon irradiating the colored crystal of KBr with light absorbed in the 265 $m\mu$ band (§ 5).

6. All these bands disappear after the electrolytic bleaching, leaving the same absorption spectrum as in the original uncolored crystal (§ 6).

First of all, it is of interest to note that similar absorption spectrum was observed by Dorendorf⁹⁾ for the crystal of KBr irradiated with X-rays. He obtained seven absorption bands of V-type as a result of X-raying at various temperatures. Wavelengths of these bands are given in Table I. Of these, V_2 , V_3 , V_5 , and V_7 bands were produced upon irradiating with X-rays at 20°C. Fig. 10 shows the absorption curve obtained by him. The similarity is rather striking in comparing this

Table I. Peak wavelengths of V band in KBr (in $m\mu$).

	V_1	V_2	V_3	V_4	V_5	V_6	V_7

curve with the curve d in Fig. 6, which shows the effect of light bleaching at room temperature for the crystal colored electrolytically with a sharp anode. Further, it is worth mentioning that the similar absorption has been observed also by Teegarden¹²⁾ for a thin film which was prepared by evaporating simultaneously both KBr and Br_2 on a quartz plate.

There is some evidence as described in § 6 that the strong absorption appearing in the region below 210 $m\mu$ will be of V-type, and it seems therefore reasonable to designate this absorption as the V_6 band. It has been suggested by Seitz that the V_6 band would be associated with the α and β bands in KBr⁴⁾. This suggestion is reasonable in view of the fact that the V_6 band has been observed by Dorendorf under X-ray irradiation by which the F centers and negative-ion vacancies are produced in the crystal. However, it seems unlikely that these (α - and β -) bands appear also in the case of the (halogen-) additive coloration in which neither the F center nor the negative-ion vacancy can be formed. Thus the species giving rise to the V_6 band may be supposed to have some of V character rather

than that of "Greek" band, though further details of its nature are not known at present.

The 265 $m\mu$ band can be assigned undoubtedly as the V_2 band, and the 240 $m\mu$ and 300 $m\mu$ bands, which are enhanced as the result of the thermal or optical bleaching of the V_2 band, are located near the V_3 and the V_7 band respectively. There was no definite indication of absorption which might be correlated to the V_4 band. In Table I are also shown these correspondences.

From the results of the present experiments, the V_3 and V_7 bands were found to be produced as the result of bleaching of the V_2 band, the absorption spectrum being similar whether bleached thermally or optically. In order to understand the mechanism of the optical bleaching, it is necessary to assume either the tunneling of holes from, or the photo-dissociation of, the V_2 center, as remarked in §5. However the first alternative seems unlikely because the quantum yield for optical bleaching is strongly dependent upon the temperature at which the irradiation has been made. Thus it might be possible to suppose that most of V_2 centers are destroyed through the process of either thermal or optical dissociation. In this way, the following is offered tentatively as an explanation for these processes.

According to Seitz model, two V_1 centers might be produced through the dissociation of V_2 center. However, at room temperature, these V_1 centers must be combined rapidly with the lattice defects such as the positive-ion vacancy or the pair vacancies, both of which are sufficiently mobile even at room temperature. The former will associate with the V_1 center to form the V_3 center, and the latter to form the V_4 center which is the anti-morph of the M center. On the other hand, a V_4 center may be formed also if one V_3 center is combined with pair vacancies and then one positive-ion vacancy is ejected from this aggregate.

Hence the following two processes are supposed to be most probable to occur through the destruction of V_2 centers at room temperature:

- (A) $V_2 \longrightarrow 2V_1$ (virtual) $\longrightarrow V_3$ or V_4 ,
 (B) $V_3 + (\text{pair vacancies}) \longrightarrow V_4 + (\text{one positive-ion vacancy ejected})$.

In the process (A), dissociation of the V_2 center will take place either thermally or optically. The process (B) may occur only through the thermal reactions. According to the results of bleaching experiments, the rate of optical process is much higher than that of the thermal process at room temperature. As described in §5, enhancement of the V_3 band is more evident in the optical bleaching than in the thermal bleaching at room temperature. This may be explained by supposing that, in the case of thermal bleaching, part of the V_3 centers produced through the process (A) will be changed gradually to the V_4 centers through the process (B).

In view of these speculations, the writer would like to identify the species giving rise to the 300 $m\mu$ band as V_4 centers. In other words, it seems more reasonable to designate this band as the V_4 band in KBr.

Acknowledgements

The writer wishes to express his sincere thanks to Prof. Y. Uchida of University of Kyoto for his continued guidance and encouragements throughout this work, and to Dr. K. Fukuda and Mr. H. Yoshimura for their kind interests and discussions.

He further appreciates the valuable and kind assistance of Mr. Y. Nishida, who is now working in the Electrical Communication Laboratory, Tokyo, in carrying out this work.

On the Magnetic Properties of Nickel Sulfide*

By Ichiro TSUBOKAWA

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai*

(Received July 14, 1958)

Magnetic measurements were performed on the specimens of powdered and single crystals of nickel sulfide having the structure of nickel arsenide type. From the results of measurements of the susceptibility, specific heat and other data, it was found that nickel sulfide is antiferromagnetic with the Néel point at 150°K. However, below 120°K, the susceptibility of the powder specimen increased with the fall of temperature and also showed a dependence of magnetic field. Such a rise in susceptibility at lower temperatures is here interpreted as due to the influence of paramagnetic islands. Correction for the atom core diamagnetism was applied to the observed susceptibilities, and from the inverse susceptibility *vs* temperature relation, the Curie constant per mol, C_M , the spin quantum number, S , and the asymptotic Curie temperature, θ , were obtained as 0.89, 1.9/2 and *ca* 3000° respectively. From the torque measurement of a single crystal of this compound, it was seen that the antiferromagnetic easy direction lies in (0001) plane of the crystal.

§ 1. Introduction

Magnetic properties of a number of chalcogenides of the transition elements with the structure of nickel arsenide type have hitherto been investigated mostly with polycrystalline specimens. Recently preparation of single crystals of such compounds has been undertaken with success and with such crystals some interesting knowledge about magneto-crystalline properties of the compounds of this type, for example, $\text{FeS}^{1)}$, $\text{Fe}_7\text{S}_8^{2)}$ and $\text{Fe}_3\text{Se}_4^{3)}$, were found. In the present investigation, we fixed our eyes on the single crystal of nickel sulfide with nickel arsenide structure and studied the antiferromagnetic behavior of this crystal which showed a peculiar behavior of parasitic susceptibility in the antiferromagnetic temperature range. The results obtained and a short discussion thereon are given in the following lines.

§ 2. Metallographic Survey and Preparation of the Specimens

Metallographic study of the binary system of nickel and sulfur was once made by Bornemann, Alsen and Willems⁴⁾. However only a few description were hitherto presented, on

the behaviors of the sulfur rich side of this system including the stoichiometric composition (fifty atomic percent of sulfur). It was reported⁵⁾ that a compound with the stoichiometric composition, NiS was able to be prepared, which was found to have three different kinds of modifications. Natural nickel sulfide and that obtained from nickel sulfate added with sulfuric acid have a rhombohedral structure (γ - NiS or millerit), while those obtained by direct synthetic method and from the acetate added with acetic acid have nickel arsenide type structure (β - NiS). The third form (α - NiS) is amorphous.

In order to obtain sufficient metallographic information on the compound of nickel sulfide with the structure of nickel arsenide type, we prepared several specimens of NiS_x including the stoichiometric composition ($x=1$). The adopted method of the preparation of the polycrystalline specimen was as follows; powders of electrolytic nickel (99.9%) and sulfur (99.9%) were mixed with the desired proportions, the mixtures were sealed in evacuated silica tubes and then heated at about 900°C for 24 hours, promoting the reaction of sulfur and nickel. During the heating process the specimen was kept at about 380°C for one week. By means of such a heat treatment the reaction tubes could be protected

* This investigation was supported in part by the Grant-in-Aid of Fundamental Scientific Research of Ministry of Education.

perfectly from the explosion due to the evaporation of sulfur. The reaction products were

The diffraction lines, whose indices satisfy the following relation, viz. $h=k+3m$, $l=2m+l$, where m and n are zero, positive or negative integers, should be missed in the case of a nickel arsenide type crystal. As the above table shows, such lines were not observable in the present case.

then cooled down in the furnace. The appearance of them showed evidence of melting at high temperatures and except for the cases of $x \leq 1.0$ the products were made up of two parts having clear boundary distinguishable by their colors. One part was of metallic gloss and the other of black color with tinged red.

Now we studied at first the crystal structure of the specimens with $x=1.0$, 0.9, 0.833 add then the separated parts with metallic gloss and those with tinged red colour with compositions $x=1.1$, 1.2, 1.3, all these results of X-ray analysis are shown in Tables I, II and III. As seen from the Table I all the diffraction lines for the compound with the composition $x=1.0$ can be indexed as those

All observed lines are indexed either as those of NiS or NiS₂. The calculated sin² θ and intensity for NiS₂ are shown in the fifth column respectively. The last two columns give indices and calculated sin² θ of Ni₃S₄.

of the nickel arsenide structure with lattice constants $a=3.39 \text{ \AA}$, $c=5.30 \text{ \AA}$ and with the axial ratio $c/a=1.56$, and it was also found that the compound showed the same structure at the temperature of liquid nitrogen. The diffraction lines for $x=0.833$ given in Table II could not easily be indexed by the present author, but based on the results of thermal analysis mentioned below, it will be supposed that these diffraction lines will be due to the compound Ni_6S_5 , as proposed by previous authors⁴. For $x=0.9$, diffraction lines of NiS were recognizable, however, other lines were seen to be identified as those of Ni_6S_5 mentioned above. The separated part with metallic gloss from the specimen with x greater than unity was also found to show only the diffraction lines of NiS . Some of the lines of the tinged red part were those of NiS while the rest of the lines could be indexed as those

of a cubic lattice with the parameter $5.65 \text{ \AA}$. As shown in Table III all these lines can be indexed by assuming the pyrite structure which is to be identified with NiS_2 found previously by Jong and Willems⁶. It was once reported by Menzer and Jong⁷ that natural leucite, whose composition is represented by Ni_3S_4 , has spinel structure with parameter $9.65 \text{ \AA}$, but for the present specimens, and diffraction lines of such type were not found. In the last two columns, the indices and calculated $\sin^2 \theta$ for Ni_3S_4 based on the reported spinel structure are shown, which do not coincide with the observed diffraction angles.

Now the thermal analyses for all the prepared reaction products were undertaken. The specific heat *vs* temperature curves are shown in Fig. 1. From these results we can recognize that for $x=0.833$, there appears an

Fig. 1. The specific heat *vs* temperature curves for the specimens $x=0.833, 0.9, 1.0, 1.1, 1.2$.

anomaly at 585°C , which coincides with the peritectoid point of Ni_6S_5 proposed formerly by Borneman and others⁴. In some cases, a peak was also found at 400°C . This peak, however, would be considered as due to the heat absorption by the evaporation of free sulfur, since the quantity of the anomalous heat absorption changed or vanished with various heat treatments of specimen. For the specimen $x=1.0$, there appeared no anomaly

up to 750°C .

From these findings it can be concluded that the compound NiS with nickel arsenide structure coexist with the compound Ni_6S_5 or with NiS_2 for excess of nickel or sulfur content respectively. Also it is to be considered that the range of compositions of nickel sulfide with nickel arsenide structure is very narrow in the phase diagram.

In order to prepare the single crystal of

NiS, the powdered specimen of NiS sealed in an evacuated silica tube was cooled down in furnace from about 900°C at the rate of half a degree per minute. In this way, single crystals larger than 15×6×6 mm³ were obtained.

§ 3. Experimental Results

(i) Magnetic susceptibility of the powder specimens

The temperature dependence of the magnetic susceptibility of nickel sulfide ($x=1$) in powder form was at first determined in the temperature range from the boiling point of liquid helium to 500°C with a magnetic balance of an automatically recording type⁸⁾. The specimens containing NiS₂ and Ni₆S₅ were also examined. These results are shown in Fig. 2.

Fig. 2. The relation between magnetic susceptibilities and temperature. Curves (a), (b) and (c) show for NiS, NiS_{1.1} (containing NiS₂) and Ni₆S₅ respectively. Diamagnetic correction were performed for curve (a).

The observed value of susceptibility was so small that it is desirable to take into account the correction coming from diamagnetism of atom cores. Such a correction was made in the following way: Diamagnetic susceptibility of several numbers of atom cores of the first transition group of ions (Sc³⁺, Ti⁴⁺, V⁵⁺, Cr⁶⁺, Mn⁷⁺) due to Pauling's result⁹⁾ was plotted in the order of atomic number as in Fig. 3a. Then diamagnetic susceptibility, χ_a for Ni¹⁰ which is considered to be the core of a nickel atom excluding the outer-shell electrons is obtained to be -3.2×10^{-6} (per mol) by means of the extrapolation of this curve. On the other hand, the susceptibility for cuprous

ion also been known to be -13.2×10^{-6} (per mol), and this value may not differ greatly from that of a hypothetical nickel ion with perfectly filled 3-d shell. If we assume that the χ_a of a nickel ion with a desired number of 3-d-electrons changes linearly from Ni¹⁰ to Cu¹⁺, then the value for Ni²⁺ is determined by the interpolation to be -11×10^{-6} mol⁻¹ (confer Fig. 3b). On the other hand, the diamagnetic correction term from S⁻² is 40×10^{-6} per mol and is much greater than the value for Ni²⁺. From these values we obtained the term of diamagnetic correction for the susceptibility of NiS as 0.72×10^{-6} gr⁻¹. The curve for NiS shown in Fig. 2 was obtained by applying the diamagnetic correction mentioned above.

As the curve shows, the susceptibility has

Fig. 3a. Diamagnetic susceptibilities for transition metal ions.

Fig. 3b. The relation between the diamagnetic susceptibility and the number of 3-d electrons.

a maximum at 150°K, then decreases during the fall of temperature but at 120°K, it reaches a minimum and again increases rapidly with the further cooling of the specimen.

(ii) *Torque measurement of the single crystal*

A magnetic torsion balance was used for the measurement of torque exerted on a single crystal specimen by the application of the magnetic field. The dimension of the single crystal used was 10 mm in length and 5×4 mm² in section. The crystal was mounted on the torsion balance with its *c*-axis normal to the suspension fiber. The changes of torque with the field direction at several temperatures are shown in Fig. 4. As is shown in the figure, the torque changes with field direction nearly proportionally to $\sin 2\theta$, θ being the angle between the *c*-axis of the crystal and the direction of the applied field. The maximum of torque occurs at $\theta = \pi/4$ at every

Fig. 4. Torque curves of NiS in the *a-c* plane. $\theta = 0^\circ$ refers to the *c*-axis and $\theta = 90^\circ$ to the *a*-axis.

Fig. 5. H^2 dependence of the maximum torque, where H is the applied magnetic field.

temperature. It was also found that the maximum torque changes proportionally to the square of the applied magnetic field. As an example, the torque value at -190°C is shown in Fig. 5.

(iii) *Specific heat at low temperatures*

The apparatus for the measurement of specific heat in the temperature range below room temperature was of an automatically recording type¹⁰. About 15 grams of the specimen was used for the measurement. The heating rate during the measurement was about 6 deg./min. The relation between the specific heat, C_p , and the temperature is shown in Fig. 6. A flat hump was seen in the vicinity of about 148°K, corresponding to the maximum of susceptibility mentioned in the preceding paragraph. The amount of the heat absorption due to this hump was estimated to be about 0.13 cal/gr or 12 cal/mol.

Fig. 6. The relation between specific heat and temperature for NiS.

§ 4. Discussion of the Experimental Results

It is to be noticed at first that any inconsistency will hardly occur among the present results if we assume that the maximum at 150°K in the susceptibility temperature curve of the compound NiS is due to the magnetic transition from antiferro. to paramagnetism. Firstly, an anomalous heat absorption due to this transformation can also be seen as a hump at 148°K in the curve of specific heat *vs* temperature mentioned above. Néel and Smart et al¹¹) have proposed the expressions of the anomalous heat capacity ΔQ and jump of specific heat ΔC_p at the Néel point as follows,

$$\Delta Q = \frac{3}{10} \frac{S^2 + (1+S)^2}{(1+S)^2} T_N \Delta C_p$$

$$\Delta C_p = \frac{5S(S+1)}{S^2 + (1+S)^2} R$$

where S , T_N and R are the spin quantum number, the Néel temperature and the gas constant respectively. Introducing the experimental values 1.9/2 for S , which will be mentioned later, and 150°K for T_N , we can obtain $\Delta Q = 225$ cal/mol and $\Delta C_p = 4$ cal/mol deg, so that the experimental value of $\Delta Q = 12$ cal/mol is about one twentyth smaller in magnitude than that expected theoretically. But we encounter frequently that experimental values are found to be far smaller than those expected from the expression above mentioned. For example, for FeO and NiO, antiferromagnetic spin ordering was confirmed by aid of neutron diffraction experiments¹²⁾ and the anomalous heat absorptions at their Néel points were found to be 60¹³⁾ and 110¹⁴⁾ cal/mol respectively, which are far smaller than the expected values from the above expressions.

Now it will be expected that the powder susceptibility of the antiferromagnetic substances decreases with the fall of temperature and at absolute zero of temperature, reaching two thirds of the values at the Néel point. Nevertheless in the present case the susceptibility begins to increase again at 120°K during the fall of temperature. Moreover there appears a magnetic field dependence of the susceptibility in the temperature range lower than the Néel point. It might seem possible at first sight to explain this fact by assuming that the specimen contains a little amount of ferromagnetic impurities, the Curie point of which lies at about 150°K. From the phase diagram above mentioned, indeed, it will be possible that the present specimen of NiS will contain a small quantity of NiS₂ or Ni₃S₂ for the excess of sulfur or nickel content. However, the χ - T curves of these compounds are of the antiferromagnetic and paramagnetic types as illustrated in Fig. 2. Therefore, the contribution from the impurities occurring from such neighboring phases can not introduce any effect of the above mentioned type on the susceptibility of nickel sulfide with the stoichiometric composition. The possibility of other kinds of ferromagnetic impurities can not be excluded so simply if the impurity distribution be in a homogeneous form in the crystal or the impurities have no magnetic anisotropy. However, such an estimation is improbable since several kinds of specimens

were prepared with nickel and sulfur of different origins and it was found that all these specimens had the same χ - T relationship. Now it will become more improbable to attribute the increase of susceptibility at low temperature to any kind of parasitic ferromagnetism, if the magnetic anisotropy mentioned above in the case of the single crystal is considered. In such a case the observed anisotropy will be of an uniaxial nature and the torque will reach asymptotically a constant value for a strong field, while in the range of weak magnetic field it will increase linearly with the field. As shown in Fig. 5, the torque is proportional to the square of the magnetic field at every temperature, so above mentioned possibility will be excluded.

Fig. 7. Temperature dependence of the difference between parallel and perpendicular susceptibilities.

From the result of the torque measurement (Fig. 4), and based on the formula for torque τ , $\tau = m/2 \cdot (\chi_c - \chi_a) H^2 \sin 2\theta$, we obtained the temperature dependence of the difference between the susceptibility in the direction of c -axis and that in the c -plane, $\chi_c - \chi_a$, as in Fig. 7. The difference decreases from the boiling point of liquid nitrogen at first gradually but it is to be noticed here that no marked discontinuity appears at the temperature 120°K of the minimum of susceptibility. On the other hand at the temperature 150°K the said difference disappears suddenly. This fact will easily be understood that the latter is the Néel point of the compound and such a rise in susceptibility in the temperature range lower than 120°K will be attributable to the existence of a kind of paramagnetic islands as in the case of CoO, which will make small contribution to the anisotropy of sus-

ceptibility. In this case the field dependence of the powder susceptibility will be caused by the antiferromagnetic part of the compound.

In the case of the nickel arsenide structure each cation is surrounded octahedrally by six neighboring anions. The crystal field due to such anion shells is pseudo-cubic type added with small trigonal symmetry, the latter greatly depending upon the axial ratio c/a and it is expected that the change of sign in the magneto-crystalline property will occur $c/a=1.63$. For NiS, the axial ratio is less than 1.63, and from the results of calculation of $L-S$ coupling energy in Ni^{2+} ion in NiS^{16} , it is concluded that the spin direction falls in c -plane. Such a conclusion coincides perfectly with the result of the torque measurement above mentioned.

Fig. 8. Temperature dependence of the difference between parallel and perpendicular susceptibility. (above the Néel point)

From the measurement of the powder susceptibility above the Néel temperature, we can obtain the relation between the inverse susceptibility and temperature, and from this relation various constants were determined as follows. The number of effective Bohr magnetons is 2.66, the spin quantum numbers S is $1.9/2$ assuming the Landé factor equal to two and the asymptotic Curie point, $-\theta$ is about $3000^\circ K$. If the compound NiS is an ideally ionic one, a nickel ion has eight electrons in outer d -shell, and S would be considered as unity. The experimental value agrees very well with the theoretical one.

K. Yoshida¹⁶⁾ discussed on the difference

$(\chi_o - \chi_a)$ above the Néel temperature, and reduced the following relation,

$$\chi_o - \chi_a = \frac{D}{kT} \left\{ \frac{3}{2} S(S+1) - \frac{3}{10} \right\}$$

where D is anisotropy constant in effective Hamiltonian. Using the experimental data (Fig. 7), we estimate $D=2.4 \text{ cm}^{-1}$. This is a reasonable value since, in this case, there exists $l-s$ coupling in addition to the spin-spin interaction.

Relaxation Spectrum of Chain High Polymeric Substances

By Tsuyoshi ONISHI* and Misazo YAMAMOTO

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto, Japan

(Received August 14, 1958)

The wedge type relaxation spectrum of amorphous chain substances having next-nearest neighbor interaction is derived. The interaction is taken in the form of special square type potential against a distance. The potential indicates that the chain has stiffness. The equation of motion is solved by normal coordinate method for Bueche's vibrating string model.

The slope of the relaxation spectrum of our model is steeper than that of ideal elastic chain model for which the slope of $-1/2$ in the log-log plot is proved, and quite coincides with the experimental data.

§ 1. Introduction

It is well known that there are generally two distinct types¹⁾ in the Relaxation Spectrum of amorphous polymers. One is the box type spectrum located in the long relaxation time region; the other is the wedge type spectrum in the short relaxation time region. From the stand point of molecular structure, the former originates from inter-chain entanglement; the latter from intra-chain relaxation, i.e., its source is in micro-Brownian motion of a chain. Theories of inter-chain relaxation have been developed by several authors²⁾ based on a model of weak rubber-like network structure. These theories however are rather qualitative in nature, and have not yet succeeded in explaining the character of the box type spectrum.

For theoretical treatment of the micro-Brownian motion following Kirkwood's theory, a Pearl Necklace model immerse in viscous liquid has been proposed³⁾. Nakada suggested that the wedge type spectrum can be explained by the Rouse model. His spectrum has a slope of $-1/2$ in the log-log plot, as has been observed for typical flexible chain substances such as amorphous polyisobutylene.

But experimental data for the slopes of many polymeric substances differ somewhat from $-1/2$. Many textile fibers have flat spectrum in the comparatively wide range of relaxation time, whereas for some flexible chain substances, the slope of the spectrum is generally a little steeper than $-1/2$ especially in short relaxation time region (Fig. 1).

For the flat spectrum, Chikahisa proposed a model and obtained less steep spectrum⁴⁾, it is still not satisfactory. The purpose of this paper is to discuss the tendency for the spectrum to become steeper. For simplicity, we adopt Bueche's vibrating string model,

Fig. 1. Wedge type relaxation spectrum of several different polymer systems at 25°C (Ferry⁶⁾). 1, 10% Polyvinylchloride in dimethyl thianthrene; 2, 20% cellulose tributyratate in dimethyl phthalate; 3, 50% polyvinyl acetate in tricresyl phosphate; 4, polyisobutylene; 5, 40% polyvinyl chloride in dimethyl thianthrene. Dashed lines are drawn with slope of $-1/2$.

instead of Rouse model which would necessitate solving the diffusion equation. Although there may be some ambiguity in Bueche's model, these two models should give the same results as far as the relaxation spectrum is concerned.

§ 2. Vibration String Model

Let $(N+1)$ spherical segments be connected by N Gaussian springs and be immersed into

* Present address: Department of Physics, Faculty of Science, Nagoya University, Nagoya, Japan.

viscous liquid in which the frictional constant is f . The equation of motion of j^{th} segment is

$$m\ddot{x}_j = -f\dot{x}_j + \Phi(j, t) - \frac{\partial V(\{x_j\})}{\partial x_j}, \quad (1)$$

$$\left(\begin{matrix} j=0, 1, 2, \dots, N \\ x, y, z \end{matrix} \right),$$

where m is the mass of a segment, $\Phi(j, t)$ external force acting on j^{th} segment at time t , and $V(\{x_j\})$ elastic potential of the chain springs, and (x, y, z) indicates that this form of the equation is satisfied by the three components x, y and z of the coordinate.

In Bueche's ideal model, V comes only from the nearest neighbor interaction, i.e.,

$$V(\{x_j\}) = (\alpha/2) \sum_j (x_j - x_{j-1})^2. \quad (2)$$

In this paper, to express the stiffness of a chain, we take into consideration the next-nearest neighbor interaction and put in the following form:

$$V(\{x_j\}) = (\alpha/2) \sum_j (x_j - x_{j-1})^2 + \lambda \sum_j \left(\frac{x_{j+1} + x_{j-1}}{2} - x_j \right)^2. \quad (3)$$

The meaning of the additional potential is easy to understand in transversal vibrational mode. For the ideal chain with potential energy (2), no difference is found in the potential energy between mode (a) and (b) in Fig. 2. But in a chain with the next-nearest neighbor interaction, potential energy becomes higher in mode (b) than in mode (a). Here λ is a constant which could give the measure of the stiffness of a chain.

Fig. 2. The meaning of our potential, Eq. (3), is easy to understand in transversal vibrational mode.

Our problem, then, is to solve Eq. (1) using internal potential (3) in the sinusoidally oscillating external force field, and to obtain the complex compliance $J^*(\omega)$ and finally to derive the relaxation spectrum.

§ 3. Normal Coordinate

Equation of motion (1) with intra-chain interaction potential (3) can be solved by the method of normal coordinate. Consider the

equation of motion for the "free" chain, viz.,

$$m\ddot{x}_j = \alpha(x_{j-1} - 2x_j + x_{j+1}) - \lambda(\frac{1}{2}x_{j-2} - 2x_{j-1} + 3x_j - 2x_{j+1} + \frac{1}{2}x_{j+2}). \quad (4)$$

with the periodical boundary condition

$$x_j = \pm x_{j+N}. \quad (5)$$

The solution of Eq. (4) under the condition (5) may be written in the form

$$x_j = \sum_{n=0}^N A_n \cos(jk_n) \exp(i\omega_n t), \quad (6)$$

where

$$k_n = (n/N)\pi, \quad (7)$$

$$\omega_n^2 = (2\kappa/m) \{ (1 - \cos k_n) - (\epsilon/2)(1 - \cos 2k_n) \} \quad (8)$$

and

$$\kappa = \alpha + 2\lambda, \quad (9)$$

$$\epsilon = \lambda/\kappa. \quad (10)$$

Here κ has a meaning of apparent elastic modulus of the chain, and ϵ may be called a "stiffness parameter" restricted in the range

$$0 \leq \epsilon \leq 1/2. \quad (11)$$

Obviously $\epsilon=0$ correspond to an ideal chain.

Eq. (1) with Eq. (3) can be solved by normal coordinate q_n :

$$x_j = \sum_{n=0}^N \sqrt{2/mN} q_n \cos(jk_n). \quad (12)$$

Then q_n must satisfy the equation

$$\ddot{q}_n + (f/m)\dot{q}_n + \omega_n q_n = F_n, \quad (13)$$

where F_n is a Fourier transform of the external force:

$$F_n = \sum_j \sqrt{2/mN} \Phi(j, t) \cos(jk_n). \quad (14)$$

Eq. (13) is an ordinary linear differential equation, and knowing $\Phi(j, t)$ it may be solved easily.

§ 4. Relaxation Spectrum

It is assumed that the system has a temporary rubber-like network structure in which the motion of the junction points follow the theorem of proportionality. Consequently external force is exerted only at the junctions, i.e., at the chain ends. Then $\Phi(j, t)$ can be taken in the form

$$\Phi(j, t) = \begin{cases} \mathcal{F} e^{i\omega t}; & j=0, \\ -\mathcal{F} e^{i\omega t}; & j=N, \\ 0; & \text{otherwise.} \end{cases} \quad (15)$$

According to Eq. (14), F_n is

$$F_n = \begin{cases} (4\mathcal{F}/\sqrt{2mN}) e^{i\omega t}; & n: \text{odd}, \\ 0; & n: \text{even}. \end{cases} \quad (16)$$

Eq. (13) gives the solution

$$q_n = \begin{cases} \frac{4\mathcal{F}}{\sqrt{2mN}} \frac{e^{i\omega t}}{\omega_n^2 - \omega^2 + i\omega f/m}; & n: \text{odd} \\ 0 & n: \text{even} \end{cases} \quad (17)$$

Complex compliance J^* can be written

$$J^* = \frac{\Delta x/R}{\nu \mathcal{F} e^{i\omega t}} = \frac{8}{\nu R m N} \sum_{n: \text{odd}} \frac{1}{\omega_n^2 - \omega^2 + i\omega f/m}, \quad (18)$$

where ν is the effective number of chains crossing the unit area of any cross section in the sample, and $\Delta x = x_0 - x_N$ denotes relative displacement of end-to-end vector of the chain, which has a length R in equilibrium state.

Eq. (1) and Eq. (18) contain the effect of inertia term $m\ddot{x}$ and ω^2 respectively. However, we may neglect these terms in the phenomenological theory of viscoelasticity. By neglecting ω^2 in the denominator of Eq. (18), we are led to complex compliance

$$J^* = \frac{8}{\nu R N f} \sum_{n: \text{odd}} \frac{\tau_n}{1 + i\omega \tau_n} \quad (19)$$

which is in agreement phenomenological expressions. Here τ_n denotes the retardation time

$$\tau_n = f/(m\omega_n^2) = \frac{f}{2\kappa} \frac{2}{(1 - \cos k_n) - (\varepsilon/2)(1 - \cos 2k_n)}. \quad (20)$$

With large value of N , summation of Eq. (19) may be approximated by the integration

$$J^* = -\frac{4}{\pi \nu R f} \int_{\tau_\alpha}^{\tau_\beta} \frac{\tau}{1 + i\omega \tau} \frac{dx}{d\tau} d\tau, \quad (21)$$

where

$$\tau = \frac{f}{2\kappa} \frac{1}{(1 - \cos x) - (\varepsilon/2)(1 - \cos 2x)} \quad (22)$$

and

$$\tau_\alpha = f/4\kappa, \quad \tau_\beta = (N/\pi)^2 (f/\alpha). \quad (23)$$

When the distribution function of retardation time $G(\tau)$ is introduced by the relation

$$J^* = -\int_0^\infty \frac{G(\tau)}{1 + i\omega \tau} d\tau, \quad (24)$$

we are led directly to the $G(\tau)$ in our system, i.e., to

$$G(\tau) = \begin{cases} \frac{1}{\pi \nu \kappa R} \frac{1}{\tau} \frac{1}{\sin x - \varepsilon \sin 2x}; & \tau_\alpha \leq \tau \leq \tau_\beta \\ 0 & \text{otherwise} \end{cases} \quad (25)$$

Relaxation time spectrurum $\Phi(\tau)$ is obtained

from Eq. (25) by using the the method described in Gross' text⁵⁾:

$$\Phi(\tau) = \frac{1}{\pi \tau} \frac{\pi G(\tau)}{[K(\tau)]^2 + [\pi G(\tau)]^2}, \quad (26)$$

where

$$K(\tau) = \int_0^\infty G(u)/(\tau - u) du. \quad (27)$$

Using the reduced quantities τ^* and $\Phi^*(\tau^*)$, i.e.,

$$\Phi(\tau) = \nu \kappa R \Phi^*(\tau^*), \quad (28)$$

$$\tau = (f/4\pi) \tau^*, \quad (29)$$

the final expression of relaxation spectrum is

$$\Phi^*(\tau^*) = \begin{cases} \frac{4}{\pi} \frac{1}{\tau^*} \frac{\pi G^*(\tau^*)}{[K^*(\tau^*)]^2 + [\pi G^*(\tau^*)]^2}; & 1 \leq \tau^* \leq \tau_\beta/\tau_\alpha \\ 0 & \text{otherwise} \end{cases} \quad (30)$$

where

$$G^*(\tau^*) = \frac{1}{2\pi} \frac{1}{\tau^*} \frac{1}{\sin x - \varepsilon \sin 2x}, \quad (31)$$

$$K^*(\tau^*) = \frac{8}{\pi} \frac{1}{(\tau^* - 1)(a_+^2 + a_-^2)} \times \left[\frac{1 + a_-^2}{2a_-} \ln \frac{a_- + \pi/2N}{|a_- - \pi/2N|} - \frac{1 - a_+^2}{a_+} \left\{ \frac{\pi}{2} - \tan^{-1} \frac{\pi}{2Na_+} \right\} \right]. \quad (32)$$

Fig. 3. Reduced relaxation spectrum $\Phi^*(\tau^*)$ for $N=10^3$ for various ε .

Here x is the function of τ^* ,

$$\tau^* = 1/\{(1 - \cos x) - (\varepsilon/2)(1 - \cos 2x)\}, \quad (33)$$

and $a_{\pm}$ is given by

$$a_{\pm} = \frac{\sqrt{(1-2\varepsilon)^2\tau^{*2} + 8\varepsilon\tau^* \pm \{(1-2\varepsilon)\tau^* - 2\}}}{2(\tau^* - 1)}. \quad (34)$$

As can be easily seen from Eqs. (28) and (29), shape of the spectrum is independent of κ and f , as long as N and ε are kept constant. In other words when κ and f change with temperature, spectrum would shift as a whole without changing its shape. This fact suggests thermorheological simplicity in the viscoelastic behavior of high polymer systems.

Fig. 3 shows curves of $\phi^*(\tau^*)$ for $N=10^3$ for various values of parameter ε . In the limit of $\varepsilon=0$, our spectrum reduces to that of Bueche which has the $-1/2$ slope. With increasing ε , the slope in the short time region increases, leaving the slope in the longer range unchanged. This tendency may be better understood when we consider that the second term of our potential has a considerable effect on vibrational mode at high frequency, i.e. on the spectrum in short relaxation time region.

Degree of polymerization N has little influence on the shape of spectrum for finite ε : the higher the degree, the more linear the shape becomes.

§ 5. Comparison with Experiment

As stated under introduction, our model is useful for rubber-like substance. Fig. 4(a) shows the experimental relaxation spectrum for polyisobutylene⁹⁾, a typical rubber-like substance, and (b) the theoretical spectrum

Fig. 4. Wedge type relaxation spectrum of polyisobutylene. (a) Experimental data⁹⁾. (b) Theoretical curve ($N=10^3$, $\varepsilon=0.47$). Dashed lines are drawn with slope of $-1/2$.

with $\varepsilon=0.47$. Good agreement is observed between these two spectra.

The values of parameters are determined by Nakada's method. By considering that, on an average, $1/3$ of the chain lies in the x direction, the effective number ν is given

$$\nu = A\rho R/3M, \quad (35)$$

where ρ : density, M : molecular weight ($M = m'N$; m' : molecular weight of a segment), R : root mean square end-to-end distance ($R = \sqrt{N}l$; l : distance between segments), and A : Avogadro's number.

For elastic modulus of the chain κ , the theory of rubber elasticity gives

$$\kappa = 3kT/l^2 \quad (36)$$

which may be used here for an approximation. For polyisobutylene $m' \sim 50$, $l \sim 3 \times 10^{-8}$ cm, $l \sim 1 \text{ \AA}$, $N \sim 10^3$, we finally get

$$\nu\kappa R \sim 10^8 \text{ dyne/cm}^2,$$

which makes the value of the spectrum reasonable.

Apparent frictional constant f can not be deduced by the known constant, but by adjusting τ_{∞} to the maximum point of wedge spectrum, f becomes

$$f \sim 10^{-5} \text{ dyne/cm/sec.}$$

Assuming that Stokes' law is valid, viscosity coefficient η is

$$\eta \approx 10^2 \sim 10^3 \text{ poise,}$$

and this value is satisfactory, as suggested by Nakada.

§ 6. Discussion and Conclusion

The relaxation spectrum of elastic chain substance having the next-nearest neighbor interaction is derived. We have used the special potential from Eq. (3). There are two advantages of our potential, viz., the stiffness of the chain can be introduced intuitively and the eigen value problem of vibration can be solved with no approximation except periodic boundary condition.

Our model gives relaxation spectra with slopes between -0.5 and -0.8 . There are

Fig. 5. Special case of $\varepsilon=1/2$ corresponds to the bending vibration of rods.

substances which have spectra steeper than our model, and although there may be some ambiguity in our model, our results suggest that the origin of the spectrum slope steeper than $-1/2$ is generally attributable to the existence of the stiffness of the chain.

The limit of $\varepsilon=1/2$ is interpreted as follows: Suppose the segments are all connected by rigid rods (see Fig. 5) and have an internal potential which is proportional to the square of the relative angle

$$V=\lambda'\sum_j\theta_j^2. \quad (37)$$

For small vibration, θ_j becomes

$$\begin{aligned} \theta_j &= \{(x_j - x_{j+1}) + (x_j - x_{j-1})\}/l \\ &= (2/l)\{x_j - (x_{j+1} + x_{j-1})/2\}, \end{aligned} \quad (38)$$

and taking $\lambda=4\lambda'/l^2$, Eq. (37) becomes equal to the special case of Eq. (3), as $\alpha=0$ when $\varepsilon=1/2$.

Accordingly, this special case corresponds to the bending vibration of rods, and the spectrum becomes linear, as shown in Fig. 2. Formally, τ_β is infinite, but as the summation of Eq. (19) can not, in this case, be approximated by the integration, continuous spectrum terminates at finite τ , and discrete relaxation time spectrum appears.

It is likely that this special case of $\varepsilon=1/2$ offer a good model for any fibrous substance composed of rigid polymeric chains. However, real fibrous substances have almost flat spectra in wide range of relaxation time, and show behavior quite contrary to our model.

Then, for the spectrum of the amorphous polymer, where does this flat spectrum belong? The box type is not suitable, because of its very long relaxation time. It may rather be assumed that it belongs in the glass state

region which is situated to the left of glass transition point where wedge type spectrum has a maximum value. If so, general schematic spectrum of amorphous chain-polymeric substances is composed of three types, viz., one wedge spectrum between two box type spectra. Some experimental data endorse this idea.

The authors express their sincere appreciation to Prof. T. Yamamoto for his constant encouragement and advice throughout this research, and thanks the members of Quantum Chemistry Laboratory of Chemistry Department of Kyoto University, and Profs. S. Onogi and H. Kawai and others in the High Polymer Research Group of Kyoto for their valuable discussions.

On the Ferromagnetic Phase in Manganese-Aluminum System

By Hiroshi KŌNO

*The Research Institute for Iron, Steel and Other Metals,
Tōhoku University, Sendai*

(Received August 15, 1958)

A metallographical investigation of manganese-aluminum system was made in the compositional range of 47% to 60% of manganese, with the results of a new hexagonal close-packed phase and a metastable tetragonal ferromagnetic phase derived therefrom. The conditions necessary for formation, structure, stability and thermal and magnetic properties of the latter phase have been studied. A discussion was also given on its magnetic properties.

§ 1. Introduction

The existence of a ferromagnetic phase in manganese-aluminum system was pointed out by Hindricks¹⁾ in 1908; Ishiwara²⁾ and later Köster³⁾ et al. made further metallographical investigations on the nature of this phase, but they failed to find its well-defined positions in the phase diagram of this binary system. Also the structure and thermal and magnetic properties of this phase have not yet been studied in detail. Moreover, there are some inconsistencies between the reported those diagrams and magnetic properties found by these authors: According to Ishiwara's phase diagram, the composition corresponding to the maximum magnetization in the ferromagnetic range lies in the two-phase region of α and δ . For the purpose of clarifying the metallographical nature of this phase, the present writer studied this system with specimens in the compositional range from 47% to 60% Mn, and with various heat treatments; basing on the results obtained, the phase diagram of this region was studied. Then the stability, the structure and thermal, magnetic and electrical properties of the ferromagnetic phase were then investigated.

§ 2. Specimens and Experimental Method

Electrolytic manganese (purity 99.9%) and aluminum pieces (99.99%) were put together in Tammann tubes in desired proportions, the inside of which was coated with alumina, and melted in an induction furnace in air; in this way mother alloys of 40 and 70 atomic per cent manganese at charge were prepared. (Chemical analysis gave 40.9% and 72.5% Mn respectively.) They were crushed, mixed in proper proportions and melted in the same

way as mentioned above and cast into bars 5 mm in diameter. The specimens thus obtained were named A_{47} , A_{48} , etc., the suffices indicating the atomic percentage of charged manganese content. During the course of melting the actual composition may be changed slightly from the initially charged one, but the shift of composition on the whole, is considered to occur regularly, so that no serious error may be introduced into a description of their physical properties in terms of charged compositions. For reference, the result of chemical analysis is given in Table I.

Table I. Chemical analysis of the specimens.

	A_{49}	A_{50}	A_{51}	A_{53}	A_{54}	A_{56}	A_{58}	A_{60}
Atomic per cent of manganese	49.1	50.1	52.2	53.8	55.1	57.1	57.9	62.5

The magnetic measurement was carried out by a ballistic method or with a magnetic balance described elsewhere⁴⁾, the X-ray structure analysis by the Debye-Scherrer method with Fe- K_{α} radiation and the thermal analysis by an adiabatic method, the detailed description of which was given by Nagasaki⁵⁾ and Takagi as well as Maeda⁶⁾. This method is considered to be good for the magnitude estimation of the latent heat for the first order transformations. For the purpose of keeping adiabatic condition at high temperatures in the present experiment, a specimen container of nickel, 5 mm in thickness, was used, and the container was further shielded by a hollow steel cylinder of 1 mm in thickness. In this way the temperature distribution in the nickel-container was homogenized. Moreover, in the present case a specimen vessel of nickel was

used, which was filled by the bar-formed specimens of proper length.

§ 3. Results of Metallographical Study

First the results of metallographical study will be described. Since the existence of a eutectoid reaction was expected above 800°C in the compositional range mentioned above, the specimens were subjected to an annealing for 1 hour at 950°C to remove the segregation, then slowly cooled to 700°C, annealed again for about 5 hours at this temperature and then cooled slowly down to room temperature in vacuum. From the fact that the specific heat *vs* temperature curves of the speci-

mens annealed for 30 minutes and those for 3~4 hours at 700°C did not differ from each other, it may be considered that the equilibrium at 700°C has almost been reached by the heat treatment mentioned above.

First of all the specific heats of these specimens were measured at the heating rate of about 2 deg./min. As shown in Fig. 1, the absorptions of heat with the latent heat type could be observed both at the temperatures 840°C and 870°C. Such measurements were repeated several times and it was found that the result here mentioned was quite reproducible. Moreover, it must be noted that the absorbed heat quantities as well as the temperatures of the heat absorption were hardly affected by the lowering of the heating rate to a value one-third of the above mentioned one during the measurement. From the results of the specific heat measurements, each absorbed heat quantity at 840°C was plotted against the composition from A_{49} to A_{57} in

Fig. 1. Specific heat *vs* temperature curves

Fig. 2. Heat of absorption at 840°C, 870°C and $\zeta \rightarrow \zeta'$ reaction. For the points ○ and △, the accuracy of the measurement is not sufficient.

Fig. 2; As can be seen from the result in Fig. 2, the absorbed heat quantity of the latent heat type is greatest at 50% and decreases linearly with the change of composition on both sides. Thus the triangle BEM was obtained. Moreover, the absorbed heat quantity for peaks A_{47} and A_{48} were also plotted, and a line $B'C'$ was obtained. Based on these results as well as on the results of X-ray analysis described in the next paragraph, it is to be proposed that the latent heat ob-

served at 840°C is due to a eutectoid reaction. The eutectoid product was named ζ' -phase. However, it is to be considered here that the two phase region $\zeta' + \zeta$, ζ being one of the reactants of the eutectoid reaction, is very narrow, so the mutual mixing of ζ and ζ' , which follows the eutectoid reaction, takes place at very narrow temperature range, and the heats of both reactions cannot be separated by the present specific heat measurement. Hence, it follows that heat quantities plotted in the compositional range between *B* and *E* in Fig. 2 represent the total evolved heats due to these two reactions. In this case the bracking point *B'* is the end point of the eutectoid line. Consequently the line *EB* represents the heat of the eutectoid reaction in the compositional range from *B* to *E*, and the range in which the eutectoid reaction occurs

Fig. 3. Phase diagram in the vicinity of MnAl. The upright and inverted black triangles $\blacktriangle$ and $\blacktriangledown$ in this figure correspond to the temperatures of appearance and disappearance of excess specific heat respectively. These points are shown by signs $\searrow$ and $\swarrow$ in Fig. 1.

extends from point *B* of about 49% Mn to point *M* of about 59.5%, and the composition of the eutectoid point *E* is 50% Mn. The temperatures at which such heat absorption occurs are indicated by Δ for various compositions in Fig. 3 and thus the eutectoid line *BEM* is obtained.

Now another supplementary fact for the above mentioned reasoning can be seen from Fig. 1 at temperatures just below 840°C.

Specific heats per mol*. C_p of the alloy A_{47} , A_{48} and A_{60} do not differ so remarkably from the value expected from the Dulong-Petit law, while those of the other specimens, the compositions of which lie in the range of the eutectoid line, show excess specific heat over the Dulong-Petit value, which is supposed to be due to the solubility change of both phases in the two-phase region $\zeta + \beta$ under *BEM* line in Fig. 3. It may be confirmed from such behaviors of the specific heats of the alloys that the two-phase region extends over the compositional range from about 49% Mn to about 59% Mn at temperatures just below 840°C. The peaks of A_{47} and A_{48} correspond to the heat absorption which is caused by the intersection of the two-phase region $\zeta + \zeta'$ (see Fig. 3).

Now, the absorbed heat quantities at 870°C are also plotted against composition in Fig. 2. As can be seen from this figure, the quantity of the latent heat absorbed at 870°C is greatest at 55% Mn and decreases linearly with change of composition on both sides of the maximum point, as is shown in Fig. 2. As can be seen from Fig. 1, the excess specific heat over the Dulong-Petit value is also seen in the specimens from A_{51} to A_{59} between 840°C and 870°C, and corresponds to the solubility change of both phases in the two phase region $\zeta' + \beta$. Based on these results, it may be supposed that the latent heat observed at 870°C is due to another eutectoid reaction. As can be estimated from Fig. 2, the range in which the eutectoid reaction mentioned here occurs extends from point *F* at about 50.5% Mn to point *K* at about 60% Mn in Fig. 3, and the eutectoid point *H* lies at 50% Mn. The temperatures at which such heat absorption occurs are also indicated against composition by $\odot$ in Fig. 3 and thus the eutectoid line *FHK* is obtained in the same way as in the case of the line *BEM*. The eutectoid product is named *h*-phase. The excess specific heat of the specimens from A_{55} to A_{60} above 870°C will be due to the solubility change of the both phases in the two-phase region $h + \beta$. The excess specific heat observed over the Dulong-Petit value in A_{51} , A_{52} and A_{53} was relatively small, which can be accounted for by assuming that

* Mol number in this case was calculated by the expression $54.93x + 26.98\{(100-x)/100\}x$ being the atomic percent of manganese.

the phase boundaries between the two-phase region $\zeta' + h$ and the single phase region ζ' - or h -phase are nearly perpendicular to the composition axis. Based on these results as well as on the results of X-ray analysis described in the following paragraph, the eutectoid reaction at 870°C was confirmed.

There are peaks in the neighbourhood of 790°C, 830°C and 930°C on the specific heat v.s. temperature curves of A_{58} , A_{59} and A_{60} respectively. The values of C_p on the lower temperature side than these peaks are somewhat larger than those expected from the Dulong-Petit law, but as will be described later, X-ray analysis suggests that these specimens are in the single phase region β . From these facts, these peaks may be accounted for by assuming that the superheated β -phase suddenly decomposes into β - and ζ' - or h -phases, and the specific heat v.s. temperature curves show the transformation of latent heat type.

The results of the X-ray analysis will now be described. All the specimens were annealed at 950°C for 20 minutes or at 750°C for 1 hour and then quenched into water, smashed into powder, and the Debye photographs were taken. No significant differences was found between diffraction patterns of the specimens quenched from 950°C in ζ' -region and those from 750°C in ζ -region. It was difficult to make structure analysis from the diffraction lines of these two phases.

Observed intensities and Bragg angles of the Debye-Scherrer lines of quenched specimen A_{54} from the region of h -phase are shown in

Table II. X-ray analysis of h -phase (quenched state).

Table II. As the table shows all the lines can be indexed, by assuming a hexagonal close-packed form. ($c/a=1.63$, $c=4.38\text{\AA}$, $a=2.69\text{\AA}$) The β -phase is of the β -Mn type structure⁷).

To determine phase boundaries, the Bragg angles θ of some strong lines of the Debye-Scherrer photographs taken with Fe- K_{α} radiation were plotted against composition. The phase boundaries were determined from the breaking points of the Bragg angle v.s. composition curve, the angle being independent of composition in the two phase region. The points N , A , G and I in Fig. 3 were obtained by this method.

From X-ray analysis of the specimens quenched from 750°C it was confirmed that Al-rich ζ -phase and M-rich β -phase coexist at 750°C in the compositional range from about 48 to 58% Mn, and the phase boundary line MN was determined by connecting M and N determined as mentions above, and the line AB was determined in the same way. The phase boundary line HJ was also determined from H and points $\blacktriangledown$ of A_{55} , A_{56} , ..., A_{60} the CB line from point B and points $\blacktriangle$ of A_{47} , A_{48} , and the DE line from point E and points $\blacktriangledown$ of A_{47} , A_{48} . The lines FG and HI were determined by connecting F and G , and H and I respectively, but the location of G and I from which the lattice parameters of ζ' -phase and h -phase respectively begin to change was rather poor in accuracy. The line KL could not be determined accurately, and the determination of its correct position will be a future problem.

§ 4. Physical Properties of the Ferromagnetic Phase and its Relation to Phase Diagram

From the magnetic measurements, both ζ - and β -phase as well as the quenched phase h were found to be non-ferromagnetic at room temperature, while the bar-formed specimens e.g. A_{54} , of the Al-rich side of h -phase which were cooled in air from 950°C were found to show ferromagnetism. The cooling rate was found to have some influence of the magnetic properties of the products. For an example, the cooling curves of A_{54} from 950°C are shown in Fig. 4 together with the room temperature values of the magnetization at $H_{\text{eff}}=1500$ Oe. From this figure the heat evolution due to the transformation h -phase $\rightarrow$ ferromag-

netic phase can be observed at about 750°C. Therefore, the rate of cooling shown by *B* or *C* for A_{54} in Fig. 4 is considered to be appropriate for hindering the decomposition of the specimen into β - and ζ -phase and permitting the formation of the ferromagnetic phase. It was also found that the magnetization of the air-cooled specimens from 950°C increases linearly with composition in the range from 50.5% to 54% Mn. In this compositional range, the relative line intensities of ζ' - and the ferromagnetic phase varied monotonously with composition, which was seen from the X-ray analysis of the air-cooled specimens.

Fig. 4. Cooling curves of A_{54} measured from 950°C. The curves for air cooling are shown by *B* or *C*. The figures under the curves are the magnetization in gauss at room temperature. (H_{eff} =1,500 Oe.)

The observed Bragg angles θ and intensities of the diffraction lines in the Debye-Scherrer photograph of the ferromagnetic A_{54} specimen are shown in Table III. As shown in this table, all lines could be indexed by assuming the lattice to be tetragonal. (see the 3rd column. $c/a=0.908$, $a=3.94\text{\AA}$, $c=3.58$) Moreover, no diffraction lines due to the β or ζ -phase were not be able to be found in the same photograph, while in the case of the Al-rich specimens the diffraction lines due to ζ' -phase were contained besides the original lines of the ferromagnetic phase and the intensity of the former increased with decreasing manganese content, while that of the latter decreases, disappearing at the composition of 50% Mn. In the Mn-rich case those due to the β -phase appeared. Hence, it is to be concluded that the specimen that could be regarded as a single phase was only A_{54} and

the others contained β and ζ' -phase. Moreover, the line intensities are calculated* by assuming the CuAu type superstructure, in which Mn and Al atoms occupy alternately successive layers perpendicular to the *c*-axis. In this case, the manganese content is a little richer than that of aluminum, so that some of Al-atoms are substituted by excess Mn-atoms. The results of calculation are shown in Table III. In this case it can easily be

shown that the structure factors of the reflections, for which the sum of *h* and *k* in the Miller index (*h*, *k*, *l*) is odd, vanish. As the table shows, the observed relative line intensity is seen to be consistent with the result of calculation. Hence, it is probable that the structure of the ferromagnetic phase is of the superstructure of CuAu type.

Now for the purpose of testing the stability of the ferromagnetic A_{54} the variation of the magnetization of the specimens due to annealing was studied in the field of H_{eff} =1750 Oe. It was found that the intensity of the magnetization was reduced to one half of its ori-

* In the calculation, the absorption due to the specimen and the decrease of the atomic scattering factor of Mn atoms due to the *K*-absorption edge were taken into consideration⁸⁾.

ginal value after annealing for ten hours at 910°C and almost disappeared after 50-hours annealing. At 650°C, it decreased to one half in one hour and disappeared after 7 hours, while at 700°C it decreased to one-half in a few minutes and disappeared after 30 minutes. By 500°C annealing, however, the magnetization was found to remain constant even after 162 hours.

The specific heat of the ferromagnetic A_{54} specimen prepared by air cooling from 950°C was measured in the temperature range from 100°C to 500°C at the heating rate of about 1.5 deg/min. and then this specimen was slowly cooled to room temperature in the apparatus. The measurement was repeated quite in the same way. As can be seen from Fig. 5, curve I, which was obtained in the first run, shows a broad minimum in the neighbourhood of 300°C, while curve II, corresponding to the second run, does not show such a minimum.

Fig. 5. Specific heat *vs.* temperature curves of the ferromagnetic A_{54} .

Measurements in subsequent runs reproduced exactly the result of the second run. However, for the specimen which was annealed for 18 hours at 400°C, the specific heat *v.s.* temperature curves did not show such a minimum and the results were quite reproducible within error of experiment at temperatures below 500°C. Therefore, the ferromagnetic A_{54} subjected to the low temperature annealing can be regarded as a stable phase with the superstructure of CuAu type in this temperature range, so we performed such a heat treatment for all of the specimens hereafter. From the thermomagnetic curve shown later, the peak at 373°C in Fig. 5 may be considered to be due to the magnetic transformation. When the measurement of the specific heat of the ferromagnetic A_{54} was extended to higher temperatures, a significant minimum of the specific heat appeared at about 700°C.

It is considered to be due to the decomposition of the ferromagnetic A_{54} into ζ - and β -phases, the accompanying evolution producing the minimum mentioned above.

The magnetization curve for powdered ferromagnetic A_{54} was taken by the ballistic method. The H^{-2} plot of specific magnetization σ is given in Fig. 6. Thus, the extrapolated saturation values at the room temperature and the boiling point of liquid nitrogen are found to be $\sigma_{\infty}=95.4$ and 99.6 respectively. Based on these two values, the extrapolated saturation value at absolute zero $\sigma_{\infty}(O)$ by the formula $\sigma_{\infty}(T)=\sigma_{\infty}(O) (1-aT^2)$ was found to be $\sigma_{\infty}(O)=100$. The thermomagnetic curve at $H_{ex.}=4500$ Oe. and the sus-

ceptibilities above the Curie temperature are shown in Fig. 7(a). In the ferromagnetic region the magnetization decreases with rising temperature, following a Weiss type curve, and disappears at the Curie point of about 370°C. On the heating curve of the susceptibility measurement, the Curie-Weiss law is seen to hold below 550°C, while at higher temperatures susceptibility decrease rapidly due to decomposition. The high temperature phase *h* shows weak paramagnetism in its stable range. It was seen from the cooling curve at the rate of about 3 deg/min. that *h*-phase remained unchanged until about 800°C and then decomposed. From these results, it is considered that the formation of the ferromagnetic phase is influenced by the cooling rate at about 800°C. The variation of specific resistance with temperature is shown in Fig. 7(b). The curve in the figure show a behavior usually observed in ordinary ferromagnetic metals below the Curie point.

§ 5. Discussions of the Magnetic Properties of the Ferromagnetic Phase

As stated above, the ferromagnetic phase discussed in the present investigation is supposed to be of the superstructure of CuAu type, which has a layer structure: Each (011) net plane contains mainly Mn or Al atoms respectively, stacking alternately in [001] direction of the crystal. Now we shall make a brief remark on the interatomic distance between two Mn atoms in the nearest neighbouring pair in a layer or in two adjacent layers. There are a few Mn atoms in an Al layer. The nearest neighbouring pair of Mn atoms in two adjacent layers has the distance 2.66Å, while that in a Mn layer has the distance 2.79Å. Now, according to the Bethe-Slater curve representing the relation between the exchange energy of magnetization and the interatomic distance, the exchange coupling between 3*d*-electrons of adjacent Mn atoms changes from antiferromagnetic to ferromagnetic at the interatomic distance of about 2.57Å. The distances between Mn atoms in our crystal are greater than this critical value, and so the occurrence of ferromagnetism in this alloy is compatible with this prediction.

The Curie temperature T_c , the absolute saturation value $\sigma_\infty(0)$, the heat of absorption per gram atom of manganese in the alloy,

ΔE due to the magnetic transformation, the spin S_x estimated from the $1/\chi$ v.s. T curve above the Curie point and the spin S_σ estimated from the saturation magnetization at $T=0$ are summarized in Table IV; these figures are obtained by assuming that all the Mn atoms are equivalent. Moreover, though not shown in Table IV, both T_c and ΔE increase with Mn content; there is an evidence that the Curie point increases by 14°C with the increase of manganese content from 54 to 55%.

Table IV.

T_c	$\sigma_\infty(0)$	ΔE	S_x	S_σ
373°C	100	320 cal	1.16	0.70

The discrepancy between the magneton number estimated from the magnetic saturation at low temperatures and that from the Curie-Weiss representation of the susceptibilities above the Curie point may be caused partly by the difficulty in saturating the magnetization, but since the latter magneton number is significantly greater than the former, there must be another reason for this, probably related to some intrinsic nature of this material. Since the $1/\chi$ v.s. T curve follows the Curie-Weiss law, we have no strong reason to consider the material to be ferrimagnetic*.

§ 6. Summary

The ferromagnetic phase in the manganese-aluminum system was investigated together with the related phase diagram. It was found that the ferromagnetic phase is formed by cooling down the *h*-phase (hexagonal loose-packed form) with about 54 atomic percent of manganese at charge to the room temperature at the cooling rate of about 10 deg./sec at 800°C. The ferromagnetic phase is metastable and has the CuAu type superstructure; the shortest distance between a pair of manganese atoms within the lattice is 2.66Å. The Curie point of this phase is about 380°C, and

* One may consider that the magnetization of this substance is smaller than that predicted from the total spin alignment because of the effective smallness of the exchange energy as is often considered in the theory of collective electron ferromagnetism.

values of the mean magnetic moment per manganese atom estimated from the low temperature saturation magnetization and the Curie-Weiss representation of the susceptibilities are 1.40 and $2.31 \mu_B$ respectively.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 12, DECEMBER 1958

Effects of High Energy Radiation on Polymers

II. End-linking and Gel Fraction

By Osamu SAITO

Faculty of Engineering, Chuo University, Tokyo

(Received September 5, 1958)

The effect of end-linking induced in polymers by high energy radiation is discussed. When cyclization does not occur, the same results are obtained as those derived by A. Charlesby, and moreover it is known that for any initial distribution the gel formation does not occur when σ is smaller than $1/4$, where σ represents the probability that an end produced by a molecular scission links with a monomer unit of another molecule. The theory also gives the average molecular weights and the average end numbers. For the initial uniform distribution the weight average molecular weight has a maximum in case $1/12 < \sigma < 1/4$, while for the initial Poisson distribution it has no maximum. The weight average end number becomes infinite at the gel point, but the number average end number does not. It is shown that the retardation of incipient gel formation is negligible when cyclization occurs. Beyond the gel point the gel part grows rapidly. The feature is studied in the cases of cross-linking and end-linking with or without cyclization, and it is shown that the gel fraction is smaller by several per cent in the case with cyclization than in the case without cyclization.

§ 1. Introduction

The effects of high energy radiation on long chain polymers are classified into cross-linking, degradation and end-linking. The first two effects were already discussed in the previous paper.¹⁾ End-linking will be studied in the first part of this paper. When the number of links produced by radiation in polymers are increased, the average molecular

weight increases resulting in the formation of insoluble part, that is, the gel. It will also be discussed how the gel fraction increases with the number of links or the radiation dose. The linkage between two monomer units belonging to the same molecule is called cyclization. It does not contribute to the increment of the molecular weight and the gel fraction. Therefore, the radiation dose

for gelation with cyclization will be larger than that without cyclization. We know from the result of the previous paper¹⁾ that the retardation of the gel formation due to the cyclization in cross-linking was negligible. However, the effect of cyclization in increasing the gel fraction beyond gel point will not be neglected. The details will be discussed later.

§ 2. End-linking without Cyclization

When some polymers are irradiated by high energy radiation, the molecular scissions will occur. A fraction of the ends newly produced will be stable, but the other fraction may combine with other monomer units at their side bonds. This type of linking is called end-linking. We will now consider how the molecular weight distribution may be affected by the end-linking induced by the radiation.

Basic assumptions made are as follows: (1) the number of scissions is proportional to the radiation dose, (2) the end-linkages take place at random and their number is proportional to the number of scission, (3) the number of end-linkages is small compared with the total number of monomer units, (4) the cyclization does not occur, and (5) the degree of polymerization can be treated as being continuous (from zero to infinity).

Let a polymer substance be exposed to a radiation with total dose R and the number of monomer units be N , then the number of scissions induced by the radiation is expressed by $N\dot{r}R$, where $\dot{r}$ represents the probability that a monomer unit is ruptured by the radiation of unit dose. The number of ends newly produced by the scissions is $2N\dot{r}R$, while the number of end-linkages is given by

$2N\sigma\dot{r}R$, where σ represents the probability that an end newly produced by the scission end-links with a monomer unit of another molecule.

It was shown in the previous paper¹⁾ that the statistical results remained unaltered even if the order of the cross-linking and the degradation was exchanged with each other. It will also be deduced from the same reasoning that the molecular weight distribution will not be altered by the exchange of the order of end-linking and scission. Therefore, we will consider that scissions occur first and then linkings follow.

When the initial molecules are linear, the new distribution function induced by the degradation is given by Eq. (29) of I¹⁾ as follows:

$$n_2(p, 0) = \left\{ n(p, 0) + 2\tau \int_p^\infty n(p, 0) dp + \tau^2 \int_p^\infty dp \int_p^\infty n(p, 0) dp \right\} e^{-p\tau}, \quad (1)$$

where p is the degree of polymerization, $\tau = \dot{r}R$ and $n(p, 0)$ represents the initial distribution. Particularly when the initial distribution is Poisson-like, i.e. $n(p, 0) = (N/u^2) \cdot \exp(-p/u)$, we obtain

$$n_2(p, 0) = N \left(\frac{1}{u} + \dot{r}R \right) e^{-p(1/u + \dot{r}R)} \quad (2)$$

Next we consider that this distribution is altered by the existence of the end-linkings. We suppose the virtual radiation dose t , which varies from zero to R , and when it increases from t to $t+dt$, $2N\sigma\dot{r}dt$ of the ends produced by the scissions link to the monomer units of other molecules. Since the number of active ends having already been end-linked at $t=t$ is $2N\sigma\dot{r}t$, the probability that an end get linked in the interval of t to $t+dt$ is

$$\frac{2N\sigma\dot{r}dt}{2N/u + 2N(R - \sigma\dot{r}t)} = \frac{\sigma\dot{r}dt}{1/u + R\dot{r} - \sigma\dot{r}t} = \omega(t)dt, \quad (3)$$

where u is the initial number average degree of polymerization. If we use $n_k(p, t)$ to express the number of the molecules which have the degree of polymerization p and the number of ends k at $t=t$, the equation representing the variation of $n_k(p, t)$ is given by

$$\frac{\partial n_k(p, t)}{\partial t} + kn_k(p, t)\omega(t) + \frac{pn_k(p, t)}{N} \int_0^\infty \sum_{l=2}^\infty in_l(l, t)\omega(t)dl \\ = \sum_{l=2}^{k-1} \int_0^p in_l(l, t)\omega(t) \frac{(p-l)n_{k-l+1}(p-l, t)}{N} dl.$$

Using the new notations $m_k(p, t) = n_k(p, t)/N$,

$$\frac{dx}{dt} = \omega(t), \quad \text{and} \quad x=0 \quad \text{at} \quad t=0, \quad (4)$$

we obtain

$$\frac{\partial m_k(p, x)}{\partial x} + km_k(p, x) + pm_k(p, x)\psi(x) = \sum_{i=2}^{k-1} \int_0^p im_i(l, x)(p-l)m_{k-i+1}(p-l, x)dl, \quad (5)$$

where

$$\psi(x) = \int_0^\infty \sum_{i=2}^\infty im_i(l, x)dl$$

means the total number of end-points. And it is expressed by the following formula because the number of end-points is increased from $2/u$ to $2(1/u + \dot{r}R)$ by molecular scissions and is decreased to $2\{1/u + \dot{r}(R - \sigma t)\}$ by end-linking,

$$\psi(x) = 2\left\{\frac{1}{u} + \dot{r}(R - \sigma t)\right\} = 2\left(\frac{1}{u} + \dot{r}R\right)e^{-x}. \quad (6)$$

If we apply the Laplace transformation

$$F(\xi, \eta, x) = \sum_{k=2}^\infty e^{-k\eta} \int_0^\infty m_k(p, x)e^{-p\xi} dp \quad (7)$$

to Eq. (5), we obtain

$$\frac{\partial F}{\partial x} = \frac{\partial F}{\partial \eta} + \psi(x) \frac{\partial F}{\partial \xi} + e^\eta \frac{\partial F}{\partial \xi} \frac{\partial F}{\partial \eta}. \quad (8)$$

The solution is given

$$\left. \begin{aligned} F(\xi, \eta, x) &= G(\xi_0, \eta_0) + \left(\xi - \xi_0 + \int_0^x \psi dx \right) \frac{\partial G}{\partial \xi_0}, \\ \xi - \xi_0 + \int_0^x \psi dx &= e^{\eta_0} (e^{-x} - 1) \frac{\partial G}{\partial \eta_0}, \\ e^{-\eta} &= e^{x - \eta_0} + (e^{-x} - 1) \frac{\partial G}{\partial \xi_0}, \end{aligned} \right\} \quad (9)$$

where $G(\xi_0, \eta_0) = F(\xi_0, \eta_0, 0)$.

Now we use the notation

$$f_{ij}(x) = \sum_{k=2}^\infty \int_0^\infty p^i k^j m_k(p, x) dp = (-1)^{i+j} \frac{\partial^{i+j} F(0, 0, x)}{\partial \xi^i \partial \eta^j}. \quad (10)$$

Then for $i=1$ and $j=0$, we obtain

$$f_{10}(x) = -\frac{\partial F(0, 0, x)}{\partial \xi} = -\left[\frac{\partial G}{\partial \xi_0} \right]_{\substack{\xi=0 \\ \eta=0}}. \quad (11)$$

As $f_{10}(x)$ is the ratio of the total monomer units and N , it must be unity. Therefore

$$\left[\frac{\partial G}{\partial \xi_0} \right]_{\substack{\xi=0 \\ \eta=0}} = -1. \quad (12)$$

Inserting Eq. (12) in the last equation of Eq. (9), we get for $\xi = \eta = 0$,

$$\eta_0 = 0. \quad (13)$$

For this value of η_0 the following equation holds

$$\left[\frac{\partial G}{\partial \xi_0} \right]_{\eta_0=0} = - \sum_{k=2}^{\infty} \int_0^{\infty} p m_k(p, 0) e^{-p \xi_0} dp = -1,$$

which gives, with the equation $f_{10}(0) = -1$,

$$\sum_{k=2}^{\infty} \int_0^{\infty} p m_k(p, 0) (1 - e^{-p \xi_0}) dp = 0.$$

Since the integrant can not be negative, we obtain

$$\xi_0 = 0. \quad (14)$$

Therefore, it is concluded that when the total number of monomer units is constant, $\xi_0 = \eta_0 = 0$ at $\xi = \eta = 0$.

For $i=j=0$, we have

$$f_{00}(x) = G(0, 0) - \int_0^x \psi dx = \left(\frac{1}{u} + iR \right) \{1 - 2(1 - e^{-x})\}.$$

Using the notation x_m , which represents the value of x at $t=R$, we get

$$f_{00}(x_m) = \frac{1}{u} + (1 - 2\sigma) iR, \quad (15)$$

and also the number average molecular weight

$$M_n(R) = M_n(0) / \{1 + (1 - 2\sigma) u iR\}. \quad (16)$$

This equation shows that the number average molecular weight does not depend on the shape of the initial distribution.

For $i=2$ and $j=0$, we get

$$f_{20}(x_m) = f_{20}(0) (1 + \gamma)^2 / [1 + (1 - 2\sigma) \gamma]^2 - 2\sigma^2 \gamma^2 (1 + \gamma) f_{20}(0) / u], \quad (17)$$

where $\gamma = u iR$ and

$$f_{20}(0) = \frac{2}{\tau} - \frac{2}{\tau^2} \int_0^{\infty} m_2(p, 0) (1 - e^{-p\tau}) dp. \quad (18)$$

Fig. 1 (a). The weight average molecular weights for initial uniform distribution.

Fig. 1 (b). The weight average molecular weights for initial uniform distribution.

we can easily obtain from Eq. (17) the weight average molecular weight

$$M_w(R) = M_w(0) \frac{(1+r)^2 f_{20}(0)}{2u} \left/ \left[\{1 + (1-2\sigma)r\}^2 - \frac{2(1+r)f_{20}(0)}{u} \sigma^2 r^2 \right] \right. \quad (19)$$

When the initial distribution is uniform, we have

$$f_{20}(0) = 4u(e^{-\gamma} - 1 + \gamma)/r^2. \quad (20)$$

And when the initial distribution is Poisson-like, we have

$$f_{20}(0) = 2u/(1+r), \quad (21)$$

and then

$$M_w(R) = M_w(0) / \{1 + (1-4\sigma)r\}. \quad (22)$$

These results are represented in Figs. 1 and 2. In Fig. 1 (a) the weight average molecular weight M_w for the case of initial uniform distribution is shown for various values of σ . It is easily derived from the preceding formulas that when σ is larger than $1/12$, the initial slope of M_w is positive, and it will also be shown from the following deduction that, when σ is smaller than $1/4$, the gel formation will not occur for any dose of irradiation. Therefore we may expect that, when σ has a value which lies between $1/12$ and $1/4$, the M_w curve will have a maximum, which is shown in Fig. 1 (b). This maximum does not occur for the initial Poisson distribution shown in Fig. 2.

Fig. 2. The weight average molecular weights for initial Poisson distribution.

Fig. 3. Weight average end number, ——— for initial Poisson distribution and - - - - for initial uniform distribution.

The value of r at the gel point is given from the relation

$$1 + r - \left\{ 2 + \sqrt{\frac{2(1+r)f_{20}(0)}{u}} \right\} \sigma r = 0. \quad (23)$$

When the initial distribution is Poisson-like, it follows

$$r_{gel} = 1/(4\sigma - 1). \quad (24)$$

This shows that the gel formation occurs when σ is larger than $1/4$. This is the result which A. Charlesby²⁾ has already obtained. It is verified that this restriction for gel formation

holds for an arbitrary initial distribution. From Eq. (18) we know that for large r it becomes

$$f_{20}(0) = \frac{2u}{r} + O\left(\frac{1}{r^2}\right).$$

Substituting this formula into Eq. (23), we obtain

$$\lim_{r \rightarrow \infty} \sigma = \frac{1}{4}.$$

It is easily shown from Eq. (23) that σ is a decreasing function of r . Then we know that for any initial distribution the gel formation does not occur when σ is smaller than $1/4$.

For $i=0$ and $j=1$, we get

$$f_{01}(x_m) = \frac{2\{1+(1-\sigma)r\}}{u}.$$

This gives the number average end number

$$E_n = \frac{f_{01}}{f_{00}} = \frac{2\{1+(1-\sigma)r\}}{1+(1-2\sigma)r}. \quad (25)$$

This result is independent of the shape of the initial distribution.

For $i=1$ and $j=1$, we get $f_{11}(x_m)$ and then the weight average end number

$$E_w = \frac{f_{11}}{f_{10}} = \frac{1+(1-\sigma)r}{\sigma r} \left[\frac{(1+r)\{1+(1-2\sigma)r\}}{\{1+(1-2\sigma)r\}^2 - (2/u)\sigma^2 r^2 (1+r)f_{20}(0)} - 1 \right]. \quad (26)$$

This value depends on the shape of the initial distribution and diverges at the gel point. When the initial distribution is Poisson-like, it gives

$$E_w = \frac{2\{1+(1-\sigma)r\}}{1+(1-4\sigma)r}. \quad (27)$$

Fig. 3 shows the curves of E_w for the Poisson and uniform distribution.

§ 3. End-linking with Cyclization

We consider in this section the effect of end-linking accompanied by cyclization. We now express by $\varphi(p, N)$ the probability that an active end, belonging to a molecule which has the degree of polymerization p , links to a monomer unit of another molecule. Then the distribution function $m_k(p, x)$ should satisfy the following equation

$$\begin{aligned} \frac{\partial m_k(p, x)}{\partial x} + k m_k(p, x) \varphi(p, N) + p m_k(p, x) \int_0^\infty \sum_{i=2}^\infty i m_i(l, x) \varphi(l, N) dl \\ = \sum_{i=2}^{k-1} \int_0^p i m_i(l, x) \varphi(l, N) (p-l) m_{k-i+1}(p-l, x) dl. \end{aligned} \quad (28)$$

For the sake of simplicity we may assume

$$\varphi(p, N) = 1 - p/N$$

Then Eq. (28) becomes

For $p \leq N$,

$$\begin{aligned} \frac{\partial m_k(p, x)}{\partial x} + k(1 - \varepsilon p) m_k(p, x) + p m_k(p, x) \int_0^N \sum_{i=2}^\infty i(1 - \varepsilon l) m_i(l, x) dl \\ = \sum_{i=2}^{k-1} \int_0^p i(1 - \varepsilon l) (p-l) m_i(l, x) m_{k-i+1}(p-l, x) dl, \end{aligned} \quad (29)$$

and for $p > N$,

$$m_k(p, x) = 0$$

where $\varepsilon = 1/N$.

If we now apply the Laplace transformation (7) to Eq. (29), we obtain

$$\frac{\partial F}{\partial x} = \frac{\partial F}{\partial \eta} + \varepsilon \frac{\partial^2 F}{\partial \xi \partial \eta} + \frac{\partial F}{\partial \xi} \{ \psi(x) - \varepsilon f_{11}(x) \} + e^\eta \left(\frac{\partial F}{\partial \xi} \frac{\partial F}{\partial \eta} + \varepsilon \frac{\partial F}{\partial \xi} \frac{\partial^2 F}{\partial \xi \partial \eta} \right). \quad (30)$$

Now assume

$$\left. \begin{aligned} F(\xi, \eta, x) &= F_0(\xi, \eta, \zeta) + \varepsilon F_1(\xi, \eta, \zeta) + \dots, \\ x &= \zeta + \varepsilon v_1(\xi, \eta, \zeta) + \dots \end{aligned} \right\} \quad (31)$$

Substituting these into Eq. (30), and determining v_1 so that F_1 is identically equal to zero, we obtain

$$\frac{\partial F_0}{\partial \zeta} = \frac{\partial F_0}{\partial \eta} + \frac{\partial F_0}{\partial \xi} \psi(\zeta) + e^\eta \frac{\partial F_0}{\partial \xi} \frac{\partial F_0}{\partial \eta}, \quad (32)$$

$$\frac{\partial F_0}{\partial \zeta} \frac{\partial v_1}{\partial \zeta} + \frac{\partial F_0}{\partial \xi} \psi'(\zeta) v_1 = f_{11}(\zeta) \frac{\partial F_0}{\partial \xi} - \left(1 + e^\eta \frac{\partial F_0}{\partial \xi} \right) \frac{\partial^2 F_0}{\partial \xi \partial \eta}. \quad (33)$$

The solution of Eq. (32) is given by Eq. (9). For $\xi = \eta = 0$ Eq. (33) becomes

$$\psi(\zeta) \frac{\partial v_1}{\partial \zeta} + \psi'(\zeta) v_1 = f_{11}(\zeta). \quad (34)$$

It gives

$$v_1(0, 0, \zeta) = \frac{1}{\psi(\zeta)} \int_0^\zeta f_{11}(\zeta') d\zeta'. \quad (35)$$

From Eqs. (31) and (32) we get

$$\left. \begin{aligned} f_{20}(x) &= f_{20}(0) \left/ \left[\{ 1 - 2(1 - e^{-\xi}) \}^2 - \frac{2(1+r)}{u} f_{20}(0)(1 - e^{-\xi})^2 \right] \right., \\ x &= \zeta + \varepsilon v_1(0, 0, \zeta). \end{aligned} \right\} \quad (36)$$

From Eq. (34) we obtain

$$v_1(0, 0, \zeta) = -\frac{1}{2\psi(\zeta)} \log \left\{ \{ (2e^{-\xi} - 1)^2 - \frac{2(1+r)}{u} f_{20}(0)(e^{-\xi} - 1)^2 \} \right\}. \quad (37)$$

When the initial distribution is Poisson-like, we get

$$f_{20}(x) = \frac{2u}{(1+r)(4e^{-\xi} - \zeta)}, \quad x = \zeta - \varepsilon \frac{ue^\xi \log(4e^{-\xi} - \zeta)}{4(1+r)}. \quad (38)$$

If we assume that the largest degree of polymerization at the gel point is kN , then

$$f_{20}(x_{gel}) \doteq k^2 N$$

and

$$-x_{gel} = \log \frac{3 + \varepsilon'}{4} + \frac{k^2 \varepsilon' \log \varepsilon'}{2(3 + \varepsilon')}, \quad (39)$$

where

$$\varepsilon' = \frac{2u\varepsilon}{(1+r)k^2}.$$

As ε and ε' are very small, the right hand side of Eq. (39) is approximately equal to $\log(3/4)$, which is the value of the case where the cyclization does not occur. This result shows that the retardation of the gel formation owing to the cyclization is negligible. Comparing this result with that in the case of cross-linking, we know that the effect of cyclization on the incipient gel formation in the end-linking is smaller than that in the cross-linking.

§ 4. Gel Fraction in Cross-Linking without Cyclization

We considered in I¹⁾ the effect of the cross-linking without cyclization and obtained the equation

$$\frac{\partial m(p, t)}{\partial t} + 2pm(p, t) = \int_0^p l(p-l)m(l, t)m(p-l, t)dl, \quad (40)$$

where $t = \bar{c}R$ and $\bar{c}$ represents the probability that a monomer unit irradiated by unit dose cross-links with a unit of another molecule, and $m(p, t)$ indicates the fraction of the molecules which have the degree of polymerization p .

In I we solved Eq. (40) under the condition that the total number of monomer units was constant. If we put

$$f_1(t) = \int_0^\infty p^1 m(p, t) dp,$$

then $f_2(t)$ is an increasing function and diverges at a certain value of t , which is called the gel point. If we assume that the total number of monomer units is constant in the region beyond the gel point, then $f_2(t)$ must be negative. Therefore, we must consider that the total number of monomer units varies beyond the gel point. Then let us assume

$$f_1(x) = 1 - g(t), \quad (41)$$

where g expresses the gel fraction. Even if the gel part exists, the distribution function $m(p, t)$ of the degree of polymerization p in the sol fraction still satisfies Eq. (40).

If we apply the Laplace transformation

$$F(s, t) = \int_0^\infty m(p, t)e^{-ps}dp, \quad (42)$$

to Eq. (40), we obtain

$$\frac{\partial F}{\partial t} = 2 \frac{\partial F}{\partial s} + \left(\frac{\partial F}{\partial s} \right)^2. \quad (43)$$

The general solution is given by

$$\left. \begin{aligned} F(s, t) &= G(s_0) - \{G'(s_0)\}^2 t, \\ s &= s_0 - 2\{1 + G'(s_0)\}t, \end{aligned} \right\} \quad (44)$$

where $G(s_0)$ is given by the initial distribution as follows

$$G(s_0) = \int_0^\infty m(p, 0)e^{-ps_0}dp. \quad (45)$$

If we put

$$f_i(t) = (-1)^i \frac{\partial^i F(0, t)}{\partial s^i}, \quad (46)$$

we get

$$f_1(t) = 1 - \frac{s_0}{2t}. \quad (47)$$

Comparing Eqs. (41) and (47) with each other, it follows

$$s_0 = 2tg. \quad (48)$$

Inserting this formula in the last equation of (44), we obtain

$$g = 1 + G'(2tg), \quad (49)$$

from which g is given as a function of t .

Fig. 4. Gel fraction.

When the initial value of g is zero, g keeps the value zero until the gel point A (Fig. 4) and lies on the branch OA where $f_1 = 1$. When f_1 maintains the value unity, f_2 is an increasing function of t . f_2 has a positive value on the branch OA and diverges at the gel point A. Therefore, g cannot remain to be zero beyond the point A and must turn on another branch AB, where f_1 is smaller than unity and f_2 is positive. Thus we know that the gel part appears at the gel point and grows as t increases.

When g has a certain value larger than zero at $t=0$, the curve of g starts at C, runs parallel to OA until point D is reached which

corresponds to the gel point A. From the point D on g increases rather rapidly.

When the initial distribution is, for instance, Poisson-like, we obtain

$$G(s_0)=1/u(1+us_0) ,$$

and Eq. (47) becomes

$$g=1-\frac{1}{(1+2utg)^2} , \tag{50}$$

which is the same as that given by A. Charlesby.⁴⁾

§ 5. Gel Fraction in Cross-Linking with Cyclization

In the case of cross-linking with cyclization,

for $p \leq N$:

$$\left. \begin{aligned} \frac{\partial m(p, t)}{\partial t} + pm(p, t) &\left\{ \int_0^N (1-\varepsilon l)lm(l, t)dt + (1-g)g \right\} \\ &+ (1-\varepsilon p)m(p, t) = \int_0^p (1-\varepsilon l)l(p-l)m(l, t)m(p-l, t)dl , \end{aligned} \right\} \tag{51}$$

for $p > N$:

$$m(p, t) = 0 .$$

The expression in the brackets of the second term of the left hand side is reduced to the following form

$$\int_0^N (1-\varepsilon l)lm(l, t)dl + (1-g)g = \int_0^\infty lm(l, t)dl + g - g^2 - \varepsilon \int_0^\infty l^2m(l, t)dl = 1 - g^2 - \varepsilon f_2(t) .$$

We know from the result of I¹⁾ that $f_2(t)$ has the greatest value k^2N at the gel point and beyond that point $f_2(t)$ decreased because the larger the molecule is the easier it is for the molecule to link to the gel part. Therefore for all the value of t , we have

$$\varepsilon f_2(t) \leq \varepsilon k^2N = k^2 .$$

Since the order of k is equal to or smaller than 10^{-2} , we may neglect the term $\varepsilon f_2(t)$, and Eq. (51) becomes,

$$\frac{\partial m(p, t)}{\partial t} + pm(p, t)(1-g^2) + pm(p, t) = \int_0^p l(p-l)m(l, t)m(p-l, t)dl . \tag{52}$$

If we apply the Laplace transformation (42) to this equation, we get

$$\frac{\partial F}{\partial t} = (2 - g^2) \frac{\partial F}{\partial s} + \left(\frac{\partial F}{\partial s} \right)^2 . \tag{53}$$

The solution is

$$F(s, t) = G(s_0) - \{G'(s_0)\}^2 t , \quad s = s_0 + \int_0^t g^2 dt - 2\{1 + G'(s_0)\}t , \tag{54}$$

where $G(s_0)$ is the same as Eq. (45). We obtain easily

$$f_1(t) = - \frac{\partial F(0, t)}{\partial s} = 1 - \left(s_0 + \int_0^t g^2 dt \right) / 2t , \tag{55}$$

and then

the integro-differential equation indicating the variation of the distribution function $m(p, t)$ was given by Eq. (1) of the previous paper.¹⁾ And we knew that, if the total number of monomer units assumed to be constant, f_2 increased with t and became infinite at a certain point where the incipient gel was formed. Beyond the point, f_1 could not keep the value unity.

If we assume, as in the last section, that the number of monomer units is not constant, that is

$$f_1(t) = 1 - g(t) ,$$

then we obtain,

$$s_0 = 2gt - \int_0^t g^2 dt. \quad (56)$$

From Eqs. (54) and (56), we get

$$g = 1 + G' \left(2gt - \int_0^t g^2 dt \right). \quad (57)$$

This corresponds to Eq. (49) for cross-linking without cyclization. Both expressions are the same until the gel point is reached. However, beyond the gel point they differ from each other.

For the initial Poisson distribution, Eq. (57) gives

$$1 + u \left(2gt - \int_0^t g^2 dt \right) = 1 / \sqrt{1-g}. \quad (58)$$

Differentiating the equation with respect to g , we obtain

$$\frac{dt}{dg} + \frac{2}{g(2-g)} t = \frac{1}{2ug(2-g)(1-g)^{3/2}}. \quad (59)$$

The solution is

$$t = \frac{2-g}{2ug} \left\{ \frac{2}{\sqrt{1-g}} + 3 \tan^{-1} \sqrt{1-g} + \frac{\sqrt{1-g}}{2-g} - \frac{10+3\pi}{4} \right\}. \quad (60)$$

The corresponding expression for the case of cross-linking without cyclization is

$$t = \frac{1}{2ug} \left(\frac{1}{\sqrt{1-g}} - 1 \right). \quad (61)$$

Fig. 5. Gel fractions in cross-linking for initial Poisson distribution.

These two expressions are shown in Fig. 5, by which we know that the cyclization retards the growth of gel fraction.

§ 6. Gel Fraction in Cross-Linking with Degradation

When cross-linking and degradation coexist, it is shown in paper I¹⁾ that the correct

statistical results are obtained by considering that all the degradations occur first and then the cross-linkings follow. If the initial distribution $m(p, 0)$ is given, the new distribution $m(p, \tau)$ due to the degradation is derived from Eq. (1). We then obtain

$$G(s_0) = \int_0^\infty m(p, \tau) e^{-ps_0} dp. \quad (62)$$

If we substitute this expression into Eq. (49), we get the gel fraction without cyclization. On the contrary, if we insert Eq. (62) in Eq. (57) we obtain the gel fraction with cyclization.

For the initial Poisson distribution $m(p, 0) = (l/u^2) \exp(-p/u)$, it gives

$$m(p, \tau) = \left(\frac{1}{u} + \tau \right)^2 e^{-(1/u+\tau)p}, \quad (63)$$

from which it follows

$$G(s_0) = \frac{(1+u\tau)^2}{u\{1+u(s_0+\tau)\}^3}. \quad (64)$$

Substituting this expression into Eq. (49), we get

$$g = 1 - \frac{(1+u\tau)^2}{\{1+u(2tg+\tau)\}^3}. \quad (65)$$

Using $\tau = \dot{r}R$ and $t = \dot{c}R$, it follows

$$g = 1 - 1 / \left\{ 1 + \frac{2u\dot{c}R}{1+u\dot{r}R} g \right\}^3. \quad (66)$$

Comparing this expression to that for no degradation:

$$g = 1 - 1 / \{1 + 2u\dot{c}Rg\}^3, \quad (67)$$

we know that if we use the formula

$$r' = \frac{u\dot{c}R}{1+u\dot{c}R} = \frac{r}{1+(\dot{c}/\dot{c})r} \quad (68)$$

in place of $u\dot{c}R$ of Eq. (67), we obtain Eq. (66). This feature was indicated by A. Charlesby.³⁾

In the case of cyclization, we obtain, by

inserting Eq. (64) in Eq. (57),

$$g = 1 - 1 / \left\{ 1 + \frac{u}{1+u\dot{c}R} \left(2gt - \int_0^t g^2 dt \right) \right\}^2. \quad (69)$$

Fig. 6 shows the g vs R curves for the several values of $\dot{c}/\dot{c}$.

§ 7. Gel Fraction in End-Linking without Cyclization

We considered in § 2 the effect of end-linking in the case where all the polymer molecules are soluble, and we know that when the total number of monomer units is constant the gel formation occurs at a certain radiation dose. After the gel is formed, we must consider sol and gel, at the same time.

Now we assume that both sol and gel part coexist and that $m_k(p, t)$ is the distribution function in the sol. A consideration analogous to that in § 2 gives the following equation

$$\begin{aligned} \frac{\partial m_k(p, t)}{\partial t} + km_k(p, t)\omega(t) + pm_k(p, t) \left\{ \int_0^\infty \sum_{i=2}^\infty im_i(l, t)dl + E_g \right\} \omega(t) \\ = \sum_{i=2}^{k-1} \int_0^p im_i(l, t)\omega(t)(p-l)m_{k-i+1}(p-l, t)dl, \end{aligned} \quad (70)$$

where E_g represents the total number of ends of the gel part. The expression

$$\int_0^\infty \sum_{i=2}^\infty im_i(l, t)dl + E_g$$

is equal to the total number of ends in the sol as well as in the gel part, which is expressed by $\phi(x)$ in § 2. If we use x defined by Eq. (4) in place of t , we obtain

$$\frac{\partial m_k(p, x)}{\partial x} + km_k(p, x) + pm_k(p, x)\phi(x) = \sum_{i=2}^{k-1} \int_0^p im_i(l, x)(p-l)m_{k-i+1}(p-l, x)dl, \quad (71)$$

which is the same as Eq. (5). Now let us solve Eq. (71) under the condition

$$\sum_{k=2}^\infty \int_0^\infty pm_k(p, x)dp = 1 - g(x). \quad (72)$$

The solution of Eq. (71) is given by Eq. (9). The solution together with Eq. (72) gives

$$\xi_0 - (1 - e^{-x})e^{\eta_0}G_{\eta_0}(\xi_0, \eta_0) = \int_0^x \phi dx, \quad e^{-\eta_0} = 1 - g(1 - e^{-x}), \quad 1 - g + G_{\xi_0}(\xi_0, \eta_0) = 0. \quad (73)$$

Eliminating ξ_0 and η_0 from Eq. (73), we get a relation between g and x . Since there exists the relation

$$e^{-x} = \frac{1 + (1 - \sigma)u\dot{c}R}{1 + u\dot{c}R}, \quad (74)$$

we can, after all, obtain a relation between g and R .

For instance, when the initial distribution is Poisson-like, it follows

Fig. 6. Gel fractions in cross-linking with degradation for initial Poisson distribution.

$$G(\xi_0, \eta_0) = \frac{(1+u\dot{r}R)^2}{u\{1+u(\xi_0+\dot{r}R)\}} e^{-2\eta_0}, \quad (75)$$

and the relation between g and R becomes

$$u\dot{r}R\{(1+2\sigma)\sqrt{1-g}-(2-3g)\sigma-1\}=1-\sqrt{1-g}. \quad (76)$$

For $\sigma=1$, it gives

$$g=1-\left(\frac{1}{3u\dot{r}R}\right)^2, \quad \text{for } u\dot{r}R > \frac{1}{3}. \quad (77)$$

This is the same as that given by A. Charlesby.²⁾ The curves of Eq. (76) for the several values of σ are given by full lines in Fig. 7.

§ 8. Gel Fraction in End-Linking with Cyclization

When cyclization takes place, the equation corresponding to Eq. (70) is as follows:

$$\begin{aligned} \frac{\partial m_k(p, t)}{\partial t} + km_k(p, t)\omega(t)\varphi(p, N) + pm_k(p, t) \left\{ \int_0^\infty \sum_{i=2}^\infty im_i(l, t)\varphi(l, N)dl + (1-g)E_g \right\} \omega(t) \\ = \sum_{i=2}^{k-1} \int_0^p im_i(l, t)\omega(t)\varphi(l, N)(p-l)m_{k-i+1}(p-l, t)dl. \end{aligned} \quad (78)$$

Using x in place of t and assuming $\varphi(p, N)=1-\varepsilon p$, we have

$$\int_0^\infty \sum_{i=2}^\infty im_i(l, x)\varphi(l, N)dl + (1-g)E_g = \psi(x) - gE_g - \varepsilon \int_0^\infty \sum_{i=2}^\infty ilm_i(l, x)dl. \quad (79)$$

The integral on the right-hand side attains its maximum value at the gel point. If we express by kN the degree of polymerization of the largest molecule at the gel point, the number of the end points of that molecule is not greater than $kN+1$. Therefore, we have, to a good approximation,

$$\int_0^\infty \sum_{i=2}^\infty ilm_i(l, x)dl \div \frac{kN(kN+1)}{N} \div k^2N.$$

Accordingly, the last term of Eq. (79) has the value of the order k^2 , which is negligible. Then Eq. (78) becomes

$$\frac{\partial m_k(p, x)}{\partial x} + km_k(p, x) + pm_k(p, x)\{\psi(x) - gE_g\} = \sum_{i=2}^{k-1} \int_0^p im_i(l, x)(p-l)m_{k-i+1}(p-l, x)dl. \quad (80)$$

As E_g is the total number of end points of the gel part, it is given as follows:

$$E_g = \psi(x) - (\text{the number of end points of sol part}) = \psi(x) + \frac{\partial F(0, 0, x)}{\partial \eta},$$

where $F(\xi, \eta, x)$ is defined by

$$F(\xi, \eta, x) = \sum_{k=2}^\infty \int_0^\infty m_k(p, x)e^{-p\xi-k\eta}dp. \quad (81)$$

If we assume now

$$\psi(x) - gE_g = \theta(x), \quad (82)$$

Eq. (80) becomes to be of the same type as Eq. (5) and the solution is given by

$$\left. \begin{aligned} F(\xi, \eta, x) &= G(\xi_0, \eta_0) + \left(\xi - \xi_0 + \int_0^x \theta(x) dx \right) \frac{\partial G}{\partial \xi_0}, \\ \xi - \xi_0 + \int_0^x \theta(x) dx &= e^{\eta_0} (e^{-x} - 1) \frac{\partial G}{\partial \eta_0}, \\ e^{-\eta} &= e^{x - \eta_0} + (e^x - 1) \frac{\partial G}{\partial \xi_0}. \end{aligned} \right\} \tag{83}$$

Therefore, we have

$$\frac{\partial F(0, 0, x)}{\partial \eta} = e^{\eta_0 - x} \frac{\partial G}{\partial \eta_0},$$

and

$$\theta(x) = (1 - g)\psi(x) - g e^{\eta_0 - x} \frac{\partial G}{\partial \eta_0}. \tag{84}$$

Considering that

$$\sum_{k=0}^{\infty} \int_0^{\infty} p m_k(p, x) dx = 1 - g(x), \tag{85}$$

we finally obtain

$$\left. \begin{aligned} \xi_0 + e^{\eta_0} (e^{-x} - 1) G_{\eta_0}(\xi_0, \eta_0) - \int_0^x \theta(x) dx &= 0, \\ e^{-\eta_0} &= 1 - g(1 - e^{-x}), \quad 1 - g + G_{\xi_0}(\xi_0, \eta_0) = 0. \end{aligned} \right\} \tag{86}$$

Elimination of ξ_0 and η_0 from these equations will give the relation between g and x .

When the initial distribution is, for instance, Poisson-like, we get from Eq. (86)

$$\frac{1 + uR}{u} \left\{ 3\sqrt{1 - g} - 1 + \frac{3g - 2}{\sqrt{1 - g}} e^{-x} \right\} - \int_0^x \theta(x) dx = 0, \tag{87}$$

and also from Eq. (84)

$$\theta(x) = \frac{2(1 + uR)}{u} \sqrt{1 - g} (\sqrt{1 - g} + g) e^{-x}. \tag{88}$$

If we assume $\sqrt{1 - g} = y$ and $e^{-x} = z$, we obtain from Eqs. (87) and (88)

$$3y - 1 + \frac{1 - 3y^2}{y} z + 2 \int_1^z y(1 + y - y^2) dz = 0, \tag{89}$$

which gives

$$y(1 - y)(1 + y + 2y^3) \frac{dz}{dy} - (1 + 3y^2)z = -3y^2. \tag{90}$$

The solution is

$$z = \frac{3y}{1 - y} (y + a)^A \{ (y + \alpha)^2 + \beta^2 \}^B e^{2\sigma \tan^{-1}((y + \alpha)/\beta)} \int_y^1 \frac{(y + a)^{-A}}{1 + y + 2y^3} \{ (y + \alpha)^2 + \beta^2 \}^{-B} e^{-2\sigma \tan^{-1}((y + \alpha)/\beta)} dy, \tag{91}$$

where

$$\begin{aligned} A &= -\frac{1 + 3a^2}{a(1 + a)(1 + 6a^2)}, & B + iC &= -\frac{\{1 + 3(\alpha + i\beta)^2\}}{(\alpha + i\beta)(1 + \alpha + i\beta)\{1 + 6(\alpha + i\beta)^2\}}, \\ a &= \sqrt[3]{\frac{\sqrt{87} + 9}{36}} - \sqrt[3]{\frac{\sqrt{87} - 9}{36}}, & \alpha &= -\frac{a}{2}, & \beta &= -\frac{\sqrt{3}}{2} \left\{ \sqrt[3]{\frac{\sqrt{87} + 9}{36}} + \sqrt[3]{\frac{\sqrt{87} - 9}{36}} \right\}. \end{aligned}$$

The broken lines in Fig. 7 are those given by Eq. (91). These indicate that the reduction of gel fraction due to cyclization amounts to more than ten per cent.

Fig. 7. Gel fractions in end-linking for initial Poisson distribution.

§ 9. Summary

The effects of high energy radiation on long chain polymers are classified into cross-linking, degradation and end-linking. The first two effects were discussed in a previous paper. The effect of end-linking without cyclization is studied in § 2 of this paper. The number and the weight average molecular weight are given in Eqs. (16) and (19) respectively. It is known that the latter diverges at the gel point, while the former does not. The radiation at the gel point is given by Eq. (23), and especially when the initial distribution is Poisson-like it reduces to Eq. (24). When the initial distribution is uniform, the weight average molecular weight has a maximum if $1/12 < \sigma < 1/4$. It is also clarified that for any initial distribution the gel formation does not occur when the value of σ is smaller than $1/4$. The number and the weight average end number are given by Eqs. (25) and (26) respectively, showing that the weight average end number diverges at the gel point, while the number average end number does not. In § 3 the effect of end-linking with cyclization is discussed and it is shown that

the retardation of the incipient gel formation is negligible. In §§ 4 and 5 the variation of the gel fraction in cross-linking is discussed. For the case where there is no cyclization, the same result as that of A. Charlesby is obtained. The effect of cyclization to gel fraction is given by Eq. (57) and Fig. 5, and the reduction of gel fraction due to cyclization amounts to several per cent. It is concluded that, in general, the radiation dose necessary to induce the same gel fraction is larger in cyclization than in no cyclization. In § 6 the gel formation by cross-linking with degradation is studied. It is again found that when there is no cyclization the same result as that of A. Charlesby is obtained. And when cyclization occurs Eqs. (66) and (69), and Fig. 6 are derived. In §§ 7 and 8 the gel fraction in end-linking is studied, giving the results indicated by Eqs. (73) and (86), and also by Fig. 7. We know from these results that the effect of cyclization on gel fraction is never neglected in the period beyond gel point. Therefore, the radiation effects determined from gel fraction or solubility will not be correct.

Acknowledgements

It is a pleasure to express my gratitude to Dr. A. Amemiya. His continued interest and support in all phases of this research are gratefully appreciated. I wish to express my gratitude to Dr. A. Harasima who reviewed the manuscript critically, and to Dr. K. Shinohara and others who are the members of the Group for the Study of Irradiated Polymers in Tokyo.

Effects of High Energy Radiation on Polymers

III. Viscosity

By Osamu SAITO

Faculty of Engineering, Chuo University, Tokyo

(Received September 5, 1958)

It was known that solubility of irradiated polymers was not free from the effect of cyclization. On the contrary, viscosity before gel point is not affected by it and it is utilized in order to investigate the effects of high energy radiation on polymers. Intrinsic viscosity is discussed first for the case where cross-linking and degradation occur. In certain cases intrinsic viscosity decreases in the initial period of irradiation, but increases in larger radiation doses, so that it has a minimum and becomes infinite at a certain radiation dose which corresponds to gel point. It is also derived that G -value of cross-linking and degradation are calculated from the intrinsic viscosity in the initial period of irradiation. An example of polyvinylchloride gives G -values whose orders of magnitude are not unreasonable. The more accurate is the measurement, the more correct values will be obtained. Intrinsic viscosity for the case where end-linking occurs is likewise discussed, and the same properties as those in cross-linking are derived. Finally we know that the gel point determined from an asymptotic behaviour of intrinsic viscosity will be more correct than that determined from an extrapolation of solubility curve.

§ 1. Introduction

It was known from the results deduced in the paper II²⁾ that the effect of cyclization induced by irradiation was negligible before gel point, while a reduction of gel fraction due to cyclization amounted to more than several per cent. Therefore, we can not neglect the effect of cyclization beyond gel point. However, if we take the effect in consideration, the theoretical treatment becomes much more complicated. Accordingly, if we analyze some properties of irradiated polymers from experimental curves of gel fraction or solubility, we can not avoid errors amounting to or more than several per cent. On the contrary, if we use experimental results before gel point, we are free from the effect of cyclization. Among many physical quantities in this stage, viscosity may be one of the best for our purpose. We will now consider the effect of high energy radiation on viscosity of polymers.

It is well known that the intrinsic viscosity $[\eta]$ of the solution of polymer, of which degree of polymerization is p , is given by

$$[\eta] \propto p^\alpha$$

where α is a constant and it has in general

a value between 1 and 1/2. For the solution of polymer, whose degree of polymerization is not uniform, the intrinsic viscosity is given by an average as follows:

$$[\eta] \propto \int_0^\infty p^{\alpha+1} m(p) dp, \quad (1)$$

where $m(p)$ denotes the normalized distribution function of molecules with respect to degree of polymerization p . When a polymer is irradiated, the occurrence of linkages between molecules and molecular scissions may vary the distribution function $m(p)$ and then the value of $[\eta]$. The value of α may not be greatly affected by irradiation, because it depends on the shape of polymer molecules in solution. Accordingly, we may assume that α has a constant value during irradiation. Especially for the initial period of irradiation, α may well be considered to be a constant. When the value of α varies greatly with radiation dose, we can easily modify the theory so that it may take in the unconstancy.

§ 2. Intrinsic Viscosity in Cross-linking

From the paper I¹⁾ and II²⁾, we know that when cyclization is neglected for cross-linking the distribution function $m(p, t)$ satisfies the

following equation

$$\frac{\partial m(p, t)}{\partial t} + 2pm(p, t) = \int_0^p l(p-l)m(l, t)m(p-l, t) dl, \quad (2)$$

where $t = \dot{c}R$, R is radiation dose and $\dot{c}$ represents the probability that a monomer unit irradiated by unit dose cross-links with a unit of another molecule. If we apply the Laplace transformation

$$f(z, t) = \int_0^\infty m(p, t) e^{-zp} dp \quad (3)$$

to Eq. (2), we obtain

$$\frac{\partial f}{\partial t} = 2 \frac{\partial f}{\partial z} + \left(\frac{\partial f}{\partial z} \right)^2. \quad (4)$$

The general solution of this differential equation is given by

$$\left. \begin{aligned} f(z, t) &= G(z_0) - \{G'(z_0)\}^2 t, \\ z &= z_0 - 2\{1 + G'(z_0)\}t, \end{aligned} \right\} \quad (5)$$

where

$$G(z_0) = \int_0^\infty m(p, 0) e^{-z_0 p} dp. \quad (6)$$

On the other hand, the numerator of the right hand side of Eq. (1) is expressed by the following complex integral (cf. Appendix I)

$$\begin{aligned} J &= \int_0^\infty p^{\alpha+1} m(p, t) dp \\ &= e^{\alpha \pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_0^\infty \frac{dz}{z^{\alpha+2}} \int_0^\infty m(p, t) e^{-zp} dp. \end{aligned} \quad (7)$$

Substituting Eq. (5) into Eq. (7), we get (cf. Appendix II)

$$J = \frac{1}{\Gamma(1-\alpha)} \int_0^\infty G''(\rho) [\rho - 2\{1 + G'(\rho)\}t]^{-\alpha} d\rho. \quad (8)$$

If the initial distribution is assumed to be Poisson-like, Eq. (8) gives (cf. Appendix II)

$$J = \frac{2u^\alpha}{\Gamma(1-\alpha)} \int_0^1 \frac{y^{\alpha+1} dy}{(1-y)^\alpha \{1 - 2uty(y+1)\}^\alpha}, \quad (9)$$

where u denotes the initial number average degree of polymerization. Intrinsic viscosity is expressed by the following formula

$$[\eta]/[\eta]_0 = J / \left\{ \frac{\alpha(\alpha+1)\pi u^\alpha}{\sin \alpha\pi \cdot \Gamma(1-\alpha)} \right\}, \quad (10)$$

where $[\eta]_0$ is the initial value of $[\eta]$.

Especially when $\alpha = 1/2$, Eq. (9) is written by complete elliptic integrals as follows:

$$J = 2\sqrt{\frac{2u}{\pi}} \{4K(k) - (3+h)E(k)\} / (1-h)\sqrt{(1+h)(3+h)}, \quad (11)$$

where

$$k^2 = \frac{(1-h)(3-h)}{(1+h)(3+h)}, \quad h = \sqrt{1-4ut}. \quad (12)$$

If we replace all u 's in Eq. (11) with

$$u/(1+u\dot{r}R), \quad (13)$$

we obtain the intrinsic viscosity in cross-linking with degradation, where $\dot{r}$ represents the probability that a monomer unit is ruptured by unit radiation dose. Fig. 1 shows the curves of intrinsic viscosity for several values of $\lambda = \dot{r}/\dot{c}$. In Fig. 2 those curves are given

Fig. 1. Intrinsic viscosity in cross-linking with degradation.

Fig. 2. Intrinsic viscosity in cross-linking with degradation.

in log-log scale. Particularly when the value of λ is smaller than and nearly equal to 4, intrinsic viscosity decreases considerably first and then it increases very rapidly.

It is easily known by expanding Eq. (9) in power series of t that when λ satisfies the following relation

$$\lambda > \frac{(\alpha+2)(\alpha+7)}{6}, \quad (14)$$

the initial slope of intrinsic viscosity curve is negative. On the other hand we know from Appendix of paper I¹⁾ that gel formation occurs when λ satisfies the relation

$$\lambda < 4. \quad (15)$$

Therefore, for λ satisfying the relation

$$4 > \lambda > (\alpha+2)(\alpha+7)/6, \quad (16)$$

intrinsic viscosity decreases first and then increases, and at a certain value of t it becomes infinite. Thus we know that intrinsic viscosity curve has a minimum when λ satisfies Eq. (16) and that even if intrinsic viscosity decreases at the initial period of irradiation, gel formation may occur. The reason is that intrinsic viscosity is dropped first by molecular scissions, at the same time, however the distribution of molecular sizes is varied gradually by cross-linking and in the later period of irradiation the effect of the latter overcomes that of the former, resulting in the gel formation. Therefore, we must measure accurately the value of λ in order that we may decide whether a certain polymer will cross-link or not.

If we expand intrinsic viscosity in a power series of t , we obtain

$$[\eta]/[\eta]_0 = 1 + a_1 ut + a_2 (ut)^2 + \dots, \quad (17)$$

where

$$a_1 = \alpha \left\{ \frac{(\alpha+2)(\alpha+7)}{6} - \lambda \right\},$$

$$a_2 = \frac{\alpha(\alpha+1)}{2} \left\{ \frac{(\alpha+2)(\alpha+3)(\alpha+7)(\alpha+14)}{90} - \frac{(\alpha+2)(\alpha+7)}{3} \lambda + \lambda^2 \right\}.$$

When we approximate the initial portion of experimental curve of intrinsic viscosity with a parabola

$$[\eta]/[\eta]_0 = 1 + A_1 uR + A_2 (uR)^2, \quad (18)$$

and determine the value of A_1 and A_2 , we obtain the relations

$$a_1 \dot{c} = A_1 \quad \text{and} \quad a_2 \dot{c}^2 = A_2. \quad (19)$$

If we know the value of α , we get the value of $\dot{c}$ and λ by solving these simultaneous equations. In the paper I¹⁾ the value of radiation dose at gel point R_g was given by

$$R_g = 1/u\dot{c}(4-\lambda). \quad (20)$$

Then we know that when the value of α is not given, we get $\dot{c}$, λ and α by measuring R_g , determining A_1 and A_2 and solving simultaneous equations (19) and (20). When the value of u instead of α is not known, we can likewise obtain it.

Fig. 3. Intrinsic viscosity of polyvinylchloride.

For example, the intrinsic viscosity curves of polyvinylchloride measured by H. Hozo³⁾ are given in Fig. 3. A sample of polyvinylchloride was irradiated in air by γ -ray of Co-60 and the other sample was irradiated in nitrogen gas. The value of u for both samples is 882 and the value of α is 0.85. The analysis gives for the first sample

$$\dot{c} = 1.6 \times 10^{-10} r^{-1}, \quad \lambda = 4.5$$

which give $\dot{c} = 7.2 \times 10^{-10} r^{-1}$ and G -value of cross-linking G_c and degradation G_r as follows:

$$G_c = 2.6, \quad G_r = 12.$$

Those values for the other sample are

$$\dot{c} = 1.7 \times 10^{-10} r^{-1}, \quad \lambda = 4.4, \quad \dot{c} = 7.4 \times 10^{-10} r^{-1},$$

$$G_c = 2.8, \quad G_r = 12.$$

The orders of those G -values are not unreasonable. If the experiments were performed carefully in the initial period of irradiation, G -values would be given accurately.

§ 3. Intrinsic Viscosity in End-linking

Let us now consider the case where end-linking occurs in an irradiated polymer. We know from the results of paper II²⁾ that the effect of cyclization is negligible before gel point and the normalized distribution function $m_x(p, x)$, which denotes the fraction of mole-

cules having degree of polymerization p and number of end points k , satisfies following equation

$$\frac{\partial m_k(p, x)}{\partial x} + km_k(p, x) + pm_k(p, x)\psi(x) = \sum_{l=2}^{k-1} \int_0^p im_l(l, x)(p-l)m_{k-l+1}(p-l, x) dl, \quad (21)$$

where

$$e^{-x} = \{1 + u\dot{r}(R - \sigma t)\} / (1 + u\dot{r}R), \quad (22)$$

$$\psi(x) = \frac{2}{u} + 2\dot{r}(R - \sigma t), \quad (23)$$

t is a variable varying from 0 to R , and σ is the probability that an end produced by a molecular scission end-links with a monomer unit.

If we apply the Laplace transformation

$$F(\xi, \eta, x) = \sum_{k=2}^{\infty} e^{-k\eta} \int_0^{\infty} m_k(p, x) e^{-\xi p} dp \quad (24)$$

to Eq. (21), we obtain

$$\frac{\partial F}{\partial x} = \frac{\partial F}{\partial \eta} + \psi(x) \frac{\partial F}{\partial \xi} + e^{\eta} \frac{\partial F}{\partial \xi} \frac{\partial F}{\partial \eta}. \quad (25)$$

The general solution is given by

$$\left. \begin{aligned} F(\xi, \eta, x) &= G(\xi_0, \eta_0) + \left\{ \xi - \xi_0 + \int_0^x \psi(x) dx \right\} \frac{\partial G}{\partial \xi_0}, \\ \xi - \xi_0 + \int_0^x \psi(x) dx &= e^{\eta_0}(e^{-x} - 1) \frac{\partial G}{\partial \eta_0}, \\ e^{-\eta} &= e^{x-\eta_0} + (e^x - 1) \frac{\partial G}{\partial \xi_0}, \end{aligned} \right\} \quad (26)$$

where

$$G(\xi_0, \eta_0) = F(\xi_0, \eta_0, 0).$$

Intrinsic viscosity in end-linking is given by

$$\frac{[\eta]}{[\eta]_0} = \frac{\sum_{k=2}^{\infty} \int_0^{\infty} p^{\alpha+1} m_k(p, x) dp}{\sum_{k=2}^{\infty} \int_0^{\infty} p^{\alpha+1} m_k(p, 0) dp}, \quad (27)$$

The numerator of right hand side is transformed to the following form (cf. Appendix III)

$$\begin{aligned} J &= \sum_{k=2}^{\infty} \int_0^{\infty} p^{\alpha+1} m_k(p, x) dp \\ &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_C \frac{F(z, 0, x)}{z^{\alpha+2}} dz \\ &= \frac{1}{\Gamma(1-\alpha)(1-e^{-x})} \int_0^{\infty} \frac{e^{-\eta_0}}{\xi^{\alpha}} \frac{(e^x - 1)G_{\xi_0 \eta_0}}{e^{x-\eta_0} - (e^x - 1)G_{\xi_0 \eta_0}} d\xi_0. \end{aligned} \quad (28)$$

For the initial Poisson distribution, we get

$$G(\xi_0, \eta_0) = \frac{\gamma^2}{\gamma + \xi_0} e^{-2\eta_0},$$

where $r=1/u+\dot{r}R$. Substituting this expression into Eq. (28), we obtain

$$J = \frac{2e^{\alpha x}}{\Gamma(1-\alpha)r^\alpha} \int_0^1 \frac{y^{\alpha+1} dy}{(1-y)^\alpha \{1-3(e^x-1)y\}^\alpha}$$

when $\alpha=1/2$, J is expressed by complete elliptic integrals:

$$J = \frac{2e^{x/2}}{\Gamma(1/2)\sqrt{r}} \int_0^1 \frac{y^{3/2}}{\sqrt{(1-y)(1-k^2y)}} dy$$

$$= \sqrt{\frac{u}{\pi}} \frac{2}{3k^4\sqrt{1+(1-\sigma)u\dot{r}R}} \{(k^2+2)K(k) - 2(k^2+1)E(k)\}, \quad (30)$$

where

$$k^2 = 3(e^x - 1) = 3\sigma u\dot{r}R / \{1 + (1-\sigma)u\dot{r}R\}.$$

And for $R=0$, we get

$$J = \frac{3}{8} \sqrt{\pi u}.$$

Fig. 4 shows the curves of intrinsic viscosity

Fig. 4. Intrinsic viscosity in end-linking.

Fig. 5. Intrinsic viscosity in end-linking.

with respect to $u\dot{r}R$. For the value of σ satisfying the following relation

$$\frac{1}{4} < \sigma < \frac{2}{7},$$

intrinsic viscosity has a minimum. The behaviour of intrinsic viscosity, particularly when the value of σ is about $1/4$, is represented in Fig. 5. These curves have the same behaviour as those in Fig. 2.

In order to determine accurately the value of σ for an arbitrary value of α , we expand the expression (29) in a power series of R , namely

$$[\eta]/[\eta]_0 = 1 + b_1 u\dot{r}R + b_2 (u\dot{r}R)^2 + \dots, \quad (32)$$

where

$$b_1 = \alpha\{\sigma(\alpha+3)-1\},$$

$$b_2 = \frac{\alpha(\alpha+1)}{2} \left\{ \frac{3}{4} \sigma^2(\alpha+2)(\alpha+3) - 2\sigma(1-\sigma)(\alpha+2) + (1-\sigma)^2 \right\}.$$

If we approximate the experimental values of intrinsic viscosity in the initial period of irradiation by a parabola

$$[\eta]/[\eta]_0 = 1 + B_1 uR + B_2 (uR)^2,$$

we obtain simultaneous equations

$$b_1 \dot{r} = B_1 \text{ and } b_2 \dot{r}^2 = B_2. \quad (33)$$

From these equations $\dot{r}$ and σ will be determined, when the value of α is known. If the value of α is not known, we need one more equation, which is given by²⁾

$$R_0 = 1/u\dot{r}(4\sigma-1). \quad (34)$$

The last Eq. (34) may also be used in order to test the validity of our theory.

If we put $\sigma=1/\lambda$ or $\sigma\dot{r}=\dot{c}$, Eq. (34) coincides with Eq. (20). And when $\alpha=1$, Eq. (17) is equal to Eq. (32). We can not distinguish

between cross-linking and end-linking by measuring intrinsic viscosity in this case. When α satisfies the relation $1/2 \leq \alpha < 1$, Eqs. (17) and (32) would not coincide with each other, even if put the relation $\sigma\dot{r} = \dot{c}$. However, the discrepancy being less than ten per cent, it is difficult to distinguish between them. For the radiation dose which is not small, the value of intrinsic viscosity for cross- and end-linking may differ considerably from each other. In such cases we must perform numerical integration of Eqs. (9) and (29). The results will be reported later.

§ 4. Determination of Gel Point

The dose of gel point is usually determined by extrapolating the solubility curve. It is, however, very difficult to measure accurately the solubility of polymer. The sol part closed in gel part by linkages and cyclizations may not be neglected. Therefore, the gel point determined from solubility measurement will not be correct. The dose of gel point R_g is necessary, in order to calculate G -values or to distinguish between cross- and end-linking. It must, therefore, be given accurately. For this purpose we may use the method to determine the dose R_g by intrinsic viscosity.

We know that intrinsic viscosity becomes infinite when the radiation dose R is equal to R_g . Eqs. (9) and (29) indicate us that intrinsic viscosity has the following asymptotic formula, which has the same form for both cross-linking and end-linking. For $\alpha \approx 1/2$, it is

$$[\eta]/[\eta]_0 \propto (R_g - R)^{-(2\alpha-1)}, \quad \text{for } R \doteq R_g \quad (35)$$

and for $\alpha = 1/2$, it is

$$[\eta]/[\eta]_0 \propto -\log(R_g - R), \quad \text{for } R \doteq R_g. \quad (36)$$

If we, for $\alpha \approx 1/2$, choose $\{[\eta]_0/[\eta]\}^{1/(2\alpha-1)}$ as ordinate and R as abscissa, measured values will be plotted on a straight line. We can easily obtain the dose of gel point R_g from the intersection of this line and abscissa. We must take care of the fact that the value of α in Eq. (35) may differ from that before irradiation. We may use as the value of α in Eqs. (19) and (33) the value before irradiation, but we can not always use it for α in Eq. (35). The value of α of the latter case must be determined so that $\{[\eta]_0/[\eta]\}^{1/(2\alpha-1)}$ lies on a straight line. For $\alpha = 1/2$, we must

choose $e^{-[\eta]/[\eta]_0}$ as ordinate. In this case, the plotted line will not be a straight line, but a curve crosses abscissa vertically. The intersection gives the dose R_g .

§ 5. Summary

It was known from the results deduced in the paper II²⁾ that the effect of cyclization was not neglected in the period beyond gel point. On the contrary, we can neglect the effect on viscosity before gel point, so that we can utilize intrinsic viscosity in order to investigate the effect of high energy radiation on polymers. In § 2 intrinsic viscosity is discussed for the case where cross-linking and degradation occur. When the initial distribution is Poisson-like, it is given by Eqs. (9), (10) and (13). Especially when the value of α is equal to $1/2$, intrinsic viscosity is expressed by complete elliptic integrals and shown in Figs. 1 and 2. When λ satisfies the relation (16), intrinsic viscosity has a minimum and becomes infinite at a certain dose of irradiation which gives gel point. If the value of λ is larger than 4, gel formation never occurs. We can obtain G -value of cross-linking and of degradation from measuring the intrinsic viscosity in the initial period of irradiation, that is, by solving simultaneous equations (19) and (20). An example of irradiated polyvinylchloride gives G -values, of which orders of magnitude are not unreasonable. This fact shows that our theory is applicable for cross-linking and degradation of irradiated polymers. The more accurate is the measurement of intrinsic viscosity in the initial period of irradiation, the more correct G -values will be obtained. In § 3 intrinsic viscosity for end-linking is deduced, and the expressions (27) and (28) are obtained. For the initial Poisson distribution they are expressed by Eq. (29). If we consider the case where $\alpha = 1/2$ holds, intrinsic viscosity is represented by complete elliptic integrals. The behaviour of intrinsic viscosity for end-linking represented in Figs. 4 and 5 is like that for cross-linking and degradation shown in Figs. 1 and 2. By the same method as illustrated in the case of cross-linking and degradation, we can calculate the value of $\dot{r}$ and σ , from which we can obtain G -value of degradation and end-linking. However, it is very difficult to distinguish between cross-linking and end-

linking by measuring the intrinsic viscosity in the initial period of irradiation. The behaviour of intrinsic viscosity for larger radiation doses will be useful for this purpose, but we must then perform numerical integration of Eqs. (9) and (29). The result will be reported later. We must obtain the value of radiation dose at gel point R_g in order to use Eqs. (20) and (34). The value of R_g determined from the measurement of solubility may not be accurate. For this purpose we can also utilize the measurement of intrinsic viscosity. If we choose $\{[\eta]_0/[\eta]\}^{1/(2\alpha-1)}$ as ordinate and R as abscissa, measured values will be plotted on a straight line. The intersection of the line and abscissa will give the

value of R_g .

We know from the discussion mentioned above that the effects of high energy radiation on polymers are determined fairly accurately from the measurement of intrinsic viscosity.

Fig. 6. Path of integration.

Appendix I

We will here verify Eq. (7). If the path of integration C is chosen as indicated in Fig. 6, it follows

$$\int_C \frac{dz}{z^{\alpha+2}} \int_0^\infty m(p, t) e^{-zp} dp = \int_0^\infty m(p, t) dp \int_C \frac{e^{-pz}}{z^{\alpha+2}} dz. \quad (37)$$

If we put the radius of circle QRS to be equal to r , we obtain

$$\begin{aligned} \int_{PQ} \frac{e^{-pz}}{z^{\alpha+2}} dz &= \left[-\frac{e^{-pz}}{(\alpha+1)z^{\alpha+1}} + \frac{p}{\alpha(\alpha+1)} \frac{e^{-pz}}{z^\alpha} \right]_P^Q + \frac{p}{\alpha(\alpha+1)} \int_{PQ} \frac{e^{-pz}}{z^\alpha} dz \\ &= -\frac{\alpha-pr}{\alpha(\alpha+1)r^{\alpha+1}} e^{-pr} - \frac{p^2}{\alpha(\alpha+1)} \int_r^\infty \frac{e^{-p\rho}}{\rho^\alpha} d\rho, \\ \int_{ST} \frac{e^{-pz}}{z^{\alpha+2}} dz &= -\frac{\alpha-pr}{\alpha(\alpha+1)r^{\alpha+1}} e^{-pr-2\pi\alpha i} + \frac{p^2}{\alpha(\alpha+1)} e^{-2\pi\alpha i} \int_r^\infty \frac{e^{-p\rho}}{\rho^\alpha} d\rho, \\ \int_{QRS} \frac{e^{-pz}}{z^{\alpha+2}} dz &= -\frac{\alpha-pr}{\alpha(\alpha+1)r^{\alpha+1}} e^{-pr}(e^{-2\pi\alpha i}-1) \\ &\quad + \frac{ip^2}{\alpha(\alpha+1)r^{\alpha-1}} \int_0^{2\pi} \exp\{-pre^{i\theta} + i(1-\alpha)\theta\} d\theta. \end{aligned}$$

Since the relation $1/2 \leq \alpha < 1$ holds, we obtain, for the limit $r \rightarrow 0$, the following equation

$$\begin{aligned} \int_{PQRST} &= \frac{p^2}{\alpha(\alpha+1)} (e^{-2\pi\alpha i}-1) \int_0^\infty \rho^{-\alpha} e^{-p\rho} d\rho = \frac{p^{\alpha+1}}{\alpha(\alpha+1)} (e^{-2\pi\alpha i}-1) \Gamma(1-\alpha) \\ &= \frac{2ip^{\alpha+1} e^{-\alpha\pi i} \sin \alpha\pi}{\alpha(\alpha+1)} \Gamma(1-\alpha). \end{aligned}$$

Therefore

$$\begin{aligned} e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_C \frac{dz}{z^{\alpha+2}} \int_0^\infty m(p, t) e^{-zp} dp &= \frac{\sin \alpha\pi \cdot \Gamma(\alpha+2) \Gamma(1-\alpha)}{\alpha(\alpha+1)\pi} \int_0^\infty p^{\alpha+1} m(p, t) dp \\ &= \int_0^\infty p^{\alpha+1} m(p, t) dp. \end{aligned}$$

Thus Eq. (7) is verified.

Appendix II

We will here deduce Eqs. (8) and (9). We get from the second equation of Eq. (5) the following equation

$$\frac{dz_0}{dz} = 1/\{1-2G''(z_0)t\} \quad (38)$$

Since the relation

$$\int_0^\infty pm(p, t) dp = 1$$

always holds, we obtain for $z=z_0=0$

$$G'(0) = -1. \quad (39)$$

When the absolute value of z is very small, we get from Eq. (38) that

$$z_0 = \frac{z}{1-2G''(0)t} + O(z^2). \quad (40)$$

Accordingly, the following relations are derived

$$\left. \begin{aligned} G(z_0) &= G(0) - \frac{z}{1-2G''(0)t} + O(z^2), \\ G'(z_0) &= -1 + \frac{G''(0)z}{1-2G''(0)t} + O(z^2), \\ G''(z_0) &= G''(0) + \frac{G'''(0)z}{1-2G''(0)t} + O(z^2). \end{aligned} \right\} \quad (41)$$

If we substitute these relations into Eq. (7), we obtain the following formulas

$$\begin{aligned} J_{PQ} &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_{PQ} \frac{dz}{z^{\alpha+2}} f(z, t) = -e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} H, \\ J_{ST} &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} e^{-2\pi\alpha i} H, \end{aligned}$$

where

$$H = \int_r^\infty \frac{d\rho}{\rho^{\alpha+2}} \{G(\rho_0) - G'(\rho_0)^2 t\}.$$

Then

$$\begin{aligned} J_{PQ} + J_{ST} &= -\frac{\Gamma(\alpha+2) \sin \alpha\pi}{\pi} H \\ &= -\frac{\Gamma(\alpha+2) \sin \alpha\pi}{\pi} \left\{ -\frac{1}{(\alpha+1)\rho^{\alpha+1}} [G(\rho_0) - G'(\rho_0)^2 t] \right. \\ &\quad \left. + \frac{1}{\alpha(\alpha+1)\rho^\alpha} G(\rho_0) \right\}_r^\infty + \frac{1}{\alpha(\alpha+1)} \int_r^\infty \frac{G''(\rho_0)}{\rho^\alpha} d\rho_0. \end{aligned} \quad (42)$$

Likewise we obtain

$$\begin{aligned} J_{QRS} &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_{QRS} \frac{dz}{z^{\alpha+2}} \tilde{f}(z, t) \\ &= -\frac{e^{\alpha\pi i} \Gamma(\alpha+2)}{2\pi r^{\alpha+1}} \int_0^{2\pi} e^{-i\alpha\theta} \{G(\rho_0) - G'(\rho_0)^2 t\} d\theta. \end{aligned} \quad (43)$$

Substituting Eq. (41) into Eqs. (42) and (43) and making r tend to zero, we get

$$\lim_{r \rightarrow 0} (J_{PQ} + J_{QRS} + J_{ST}) = \frac{1}{\Gamma(1-\alpha)} \int_{\rho=0}^{\rho=\infty} \frac{G''(\rho_0)}{\rho^\alpha} d\rho_0,$$

therefore

$$J = \frac{1}{\Gamma(1-\alpha)} \int_{\rho=0}^{\rho=\infty} G''(\rho_0) \{ \rho_0 - 2[1 + G'(\rho_0)]t \}^{-\alpha} d\rho_0. \quad (44)$$

We know from § 2 of the paper I¹⁾ that $\rho_0=0$ holds for $\rho=0$. On the other hand the following relation is derived from Eq. (5)

$$\frac{\partial f(\rho, t)}{\partial \rho} = - \int_0^{\infty} p m(p, t) e^{-\rho p} dp = G'(\rho_0).$$

If p_0 be an arbitrary positive number, we obtain the following relation

$$\begin{aligned} \int_{p_0}^{\infty} p m e^{-\rho p} dp &< \int_{p_0}^{\infty} p m e^{-\rho p_0} dp < \int_0^{p_0} p m e^{-\rho p} dp + e^{-\rho p_0} \left(1 - \int_0^{p_0} p m dp \right) \\ &= \int_0^{p_0} p m (e^{-\rho p} - e^{-\rho p_0}) dp + e^{-\rho p_0} \\ &= p_0 \xi m(\xi, t) (e^{-\rho \xi} - e^{-\rho p_0}) + e^{-\rho p_0}, \quad 0 < \xi < p_0 \\ &\leq p_0^2 m(\xi, t) e^{-\rho p_0} \{ e^{\rho(p_0 - \xi)} - 1 \} + e^{-\rho p_0}. \end{aligned}$$

Since the last expression converges to 0 as $\rho \rightarrow \infty$, we get

$$\lim_{\rho \rightarrow \infty} G'(\rho_0) = 0.$$

Considering Eq. (5), we derive the following equation

$$\lim_{\rho \rightarrow 0} \rho_0 = \infty. \quad (45)$$

Therefore Eq. (44) becomes

$$J = \frac{1}{\Gamma(1-\alpha)} \int_0^{\infty} G''(\rho_0) \{ \rho_0 - 2[1 + G'(\rho_0)]t \}^{-\alpha} d\rho_0.$$

When the initial distribution is Poisson-like, we have

$$G(\rho_0) = 1/u(1 + u\rho_0),$$

where u denotes the initial number average degree of polymerization. If we put $1 + u\rho_0 = 1/y$, we obtain finally

$$J = \frac{2u^\alpha}{\Gamma(1-\alpha)} \int_0^1 \frac{y^{\alpha+1} dy}{(1-y)^\alpha \{1 - 2uty(y+1)\}^\alpha}.$$

Appendix III

We will here derive Eq. (28). If we apply the relation (7), we get the following equation

$$\begin{aligned} J &= \sum_{k=2}^{\infty} \int_0^{\infty} p^{\alpha+1} m_k(p, x) dp \\ &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_0^{\infty} \frac{dz}{z^{\alpha+2}} \sum_{k=2}^{\infty} m_k(p, x) e^{-zx} dp. \end{aligned}$$

The last expression is transformed into the following formula

$$\begin{aligned} &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_0^{\infty} \frac{F(z, 0, x)}{z^{\alpha+2}} dz \\ &= e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi i} \int_0^{\infty} \frac{dz}{z^{\alpha+2}} \left\{ \left(z - z_0 + \int_0^z \psi dx \right) G_{z_0}(z_0, \eta_0) + G(z_0, \eta_0) \right\}. \end{aligned}$$

Therefore

$$\begin{aligned}
 J_{FQ} + J_{ST} &= -\frac{\Gamma(\alpha+2)}{\pi} \sin \alpha\pi \int_r^\infty \frac{d\rho}{\rho^{\alpha+2}} \left\{ \left(\rho - \rho_0 + \int_0^x \psi dx \right) G_{\rho_0}(\rho_0, \eta_0) + G(\rho_0, \eta_0) \right\} \\
 &= -\frac{\Gamma(\alpha+2)}{\pi} \sin \alpha\pi \left\{ \left| -\frac{1}{(\alpha+1)\rho^{\alpha+1}} \left[\left(\rho - \rho_0 + \int_0^x \psi dx \right) G_{\rho_0}(\rho_0, \eta_0) + G(\rho_0, \eta_0) \right] \right|_{\rho=r}^{\rho=\infty} \right. \right. \\
 &\quad \left. \left. + \frac{1}{\alpha} \int_r^\infty \frac{1}{\rho^{\alpha+1}} \left[G_{\rho_0}(\rho_0, \eta_0) + \left(\rho - \rho_0 + \int_0^x \psi dx \right) G_{\rho_0\rho_0}(\rho_0, \eta_0) \right] \frac{d\rho_0}{d\rho} d\rho \right\} \right. \\
 &= -\frac{\Gamma(\alpha+2)}{\pi} \sin \alpha\pi \left\{ \left| -\frac{1}{(\alpha+1)\rho^{\alpha+1}} \left[\left(\rho - \rho_0 + \int_0^x \psi dx \right) G_{\rho_0}(\rho_0, \eta_0) + G(\rho_0, \eta_0) \right] \right| \right. \\
 &\quad \left. \left. - \frac{1}{\alpha(\alpha+1)} \frac{G_{\rho_0}(\rho_0, \eta_0)}{\rho^\alpha} \right|_{\rho=r}^{\rho=\infty} - \frac{1}{\alpha} \int_{\rho=r}^{\rho=\infty} \frac{G_{\rho_0\rho_0}(\rho_0, \eta_0)}{\rho^\alpha} d\eta_0 \right\}.
 \end{aligned}$$

By differentiating Eq. (26), we obtain

$$\frac{\partial F}{\partial \xi} = \frac{\partial G}{\partial \xi_0} = -\sum_{k=2}^{\infty} \int_0^{\infty} p m_k e^{-\xi p} dp.$$

The right hand side converges to 0, where ξ is real and tends to infinity. Therefore, from Eq. (26) we obtain

$$\lim_{\xi \rightarrow \infty} \frac{\partial G}{\partial \xi_0} = \lim_{\xi \rightarrow \infty} \frac{e^{-x} - e^{-\eta_0}}{1 - e^{-x}} = 0, \quad (46)$$

hence

$$\lim_{\xi \rightarrow \infty} \eta_0 = x. \quad (47)$$

From Eq. (26) the following relation holds

$$-\sum_{k=2}^{\infty} k \int_0^{\infty} m_k e^{-\xi p} dp = \frac{\partial F(\xi, 0, x)}{\partial \eta} = \left(\xi - \xi_0 + \int_0^x \psi dx \right) \frac{1}{1 - e^x}.$$

Making ξ tend to infinity, we obtain

$$0 = \left(\xi - \xi_0 + \int_0^x \psi dx \right) \frac{1}{1 - e^x},$$

therefore the following equation is derived

$$\lim_{\xi \rightarrow \infty} \xi_0 = \infty. \quad (48)$$

From these results we get

$$\lim_{\xi \rightarrow \infty} G(\xi_0, \eta_0) = \lim_{\substack{\xi_0 \rightarrow \infty \\ \eta_0 \rightarrow x}} \sum_{k=2}^{\infty} \int_0^{\infty} m(p, 0) e^{-\xi_0 p - k\eta_0} dp = 0, \quad (49)$$

and then

$$\begin{aligned}
 J_{FQ} + J_{ST} &= -\frac{\Gamma(\alpha+2)}{\pi} \sin \alpha\pi \left\{ \frac{1}{(\alpha+1)r^{\alpha+1}} \left[\left(r - \rho_0 + \int_0^x \psi dx \right) G_{\rho_0}(\rho_0, \eta_0) \right. \right. \\
 &\quad \left. \left. + G(\rho_0, \eta_0) \right] + \frac{1}{\alpha(\alpha+1)} \frac{G_{\rho_0}(\rho_0, \eta_0)}{r^\alpha} - \frac{1}{\alpha} \int_{\rho=r}^{\rho=\infty} \frac{1}{\rho^\alpha} G_{\rho_0\rho_0}(\rho_0, \eta_0) d\eta_0 \right\}. \quad (50)
 \end{aligned}$$

As we already know from the results of §2 of the paper II²⁾ that $\rho_0 = \eta_0 = 0$ holds for $\rho = \eta = 0$, we can put for the case where $\eta = 0$ the following relations

$$\left. \begin{aligned} \rho_0 &= a\rho + O(\rho^2), \\ \eta_0 &= b\rho + O(\rho^2), \end{aligned} \right\} \quad (51)$$

where a and b are independent with ρ . If we substitute these expressions into the second and the third equation of Eq. (26), we get

$$\{B(1-e^{-x})-1\}a + (C+D)(1-e^{-x})b = -1,$$

$$A(1-e^{-x})a + \{B(1-e^{-x})-1\} = 0.$$

From these simultaneous equations a and b are solved,

$$a = \frac{1-B(1-e^{-x})}{\{B(1-e^{-x})-1\}^2 - A(C+D)(1-e^{-x})^2}. \quad (52)$$

$$b = \frac{A(1-e^{-x})}{\{B(1-e^{-x})-1\}^2 - A(C+D)(1-e^{-x})^2}. \quad (53)$$

where $A = G_{\rho_0\rho_0}(0, 0)$, $B = G_{\rho_0\eta_0}(0, 0)$, $C = G_{\eta_0\eta_0}(0, 0)$ and $D = G_{\eta_0}(0, 0)$. If we insert Eq. (51) in Eq. (50), we get

$$\begin{aligned} J_{PQ} + J_{ST} = & -\frac{\Gamma(\alpha+2)}{\pi} \sin \alpha\pi \left\{ \frac{r^{-\alpha-1}}{\alpha+1} [V + D(1-e^{-x}) - r + O(r^2)] \right. \\ & \left. + \frac{r^{-\alpha}}{\alpha(\alpha+1)} [-1 + O(r)] - \frac{1}{\alpha} \int_{\rho=r}^{\rho=\infty} \rho^{-\alpha} G_{\rho_0\eta_0}(\rho_0, \eta_0) d\eta_0 \right\}, \end{aligned} \quad (54)$$

where $V = G(0, 0)$. On the other hand, we obtain likewise

$$\begin{aligned} J_{QRS} = & e^{\alpha\pi i} \frac{\Gamma(\alpha+2)}{2\pi r^{\alpha+1}} \int_0^{2\pi} e^{-i(\alpha+1)\theta} \{V + D(1-e^{-x}) - r e^{i\theta} + O(r^2)\} d\theta \\ = & \frac{\Gamma(\alpha+2)}{\pi r^{\alpha+1}} \sin \alpha\pi \left\{ \frac{V + D(1-e^{-x})}{\alpha+1} - \frac{r}{\alpha} + O(r^2) \right\}. \end{aligned} \quad (55)$$

Ultimately J is given by

$$J = J_{PQ} + J_{QRS} + J_{ST} = \frac{\Gamma(\alpha+2)}{\alpha\pi} \sin \alpha\pi \int_{\rho=r}^{\rho=\infty} \rho^{-\alpha} G_{\rho_0\eta_0}(\rho_0, \eta_0) d\eta_0 + O(r^{1-\alpha}).$$

When r tends to zero, J becomes

$$\begin{aligned} J = & \frac{\Gamma(\alpha+2)}{\alpha\pi} \sin \alpha\pi \int_{\rho=0}^{\rho=\infty} \rho^{-\alpha} G_{\rho_0\eta_0}(\rho_0, \eta_0) d\eta_0 = \frac{1}{\Gamma(1-\alpha)(1-e^{-x})} \int_0^x \frac{e^{-\eta_0}}{\rho^\alpha} d\eta_0 \\ = & \frac{1}{\Gamma(1-\alpha)(1-e^{-x})} \int_0^\infty \frac{e^{-\eta_0}(e^x-1)G_{\rho_0\rho_0}(\rho_0, \eta_0)}{\rho^\alpha \{e^{x-\eta_0} - (e^x-1)G_{\rho_0\eta_0}(\rho_0, \eta_0)\}} d\rho_0. \end{aligned} \quad (56)$$

When the initial distribution is Poisson-like, the function G is expressed by

$$G(\rho_0, \eta_0) = \frac{r^2}{r + \rho_0} e^{-2\eta_0},$$

where $r = 1/u + iR$. If we put

$$y = \sqrt{\frac{e^{x-\eta_0}-1}{e^x-1}},$$

we obtain finally

$$J = \frac{2e^{\alpha x}}{\Gamma(1-x)} \int_0^1 \frac{y^{\alpha+1} dy}{(1-y)^\alpha \{1-3(e^x-1)y\}^\alpha}. \quad (57)$$

Acknowledgements

It is a pleasure to express my gratitude to Dr. A. Amemiya. His continued interest and support in all phases of this research are gratefully appreciated. I wish to thank Dr. A. Harasima and Dr. K. Shinohara for their direction and guidance of this problem, and

also to thank the members of the Group for the Study of Irradiated Polymers in Tokyo.

Theory of Excited Plasma Waves

By Masao SUMI

Electrical Communication Laboratory, Tokyo

(Received August 20, 1958)

The excitation of oscillations in a uniform plasma by an injected electron beam is considered. The dispersion relation for this system is derived by means of Fourier-Laplace transform method. The solutions of the dispersion relation are obtained which yield the characteristics of excited waves; the frequency, the phase velocity and the time-rate of wave-growth as functions of the wave number. It is demonstrated that the wave characteristics are varied by the influence of thermal velocity of electrons in the main plasma and by taking the ratio of electron density in the beam to that in the main plasma over a wide range of values. It is then examined that both the velocity spread in the beam and collisions in the medium have the decaying effect on the growing wave. By the use of the above results the case is also discussed where the main plasma is bounded by ideally thin sheaths.

§ 1. Introduction

We shall deal with in this work the longitudinal oscillations in a uniform main plasma excited by an electron beam injected from an external source. In the region where the electron beam passes through, the total charge is assumed to be cancelled out on the average on account of positive ions created in the medium by electron impacts. The main plasma may be supposed either unbounded or bounded by ideally thin sheaths.

The beam excitation of plasma oscillations has since been discussed by many authors. Some of them treated the waves generated by multi-stream interactions¹⁾. The problem of the beam excitation in a thermal plasma was also considered in several papers; Bohm and Gross studied in a series of their works the instability of beams of well-defined velocity and the excitation due to fast beams emitted

from an electrode²⁾. They have derived the dispersion relation and discussed about solutions only for a weak beam. The results obtained as for instabilities are qualitatively valid, but unsatisfactory from a quantitative point of view, and besides the stationary solutions discussed there are open to criticism, because they have used the substitution analysis to get the dispersion relation. Akhiezer and Feinberg have also led the dispersion relation, but have not studied the detailed features on oscillations³⁾. The more quantitative treatment has been carried out by Lampert⁴⁾, who obtained the rate of growth-in-time for the case of thermal velocity negligible in the main plasma and also the amplification factor for traveling plasma waves. It is found, however, that the results attained were restricted only in the weak beam limit and the whole characteristics of excited waves were not examined.

Lately the author has also tried to get the characteristics of excited waves⁶⁾. But the approximate procedure then employed was unsatisfactory and therefore the more accurate and detailed study will be developed in this paper.

In the study of plasma waves has been widely used the method of substitution analysis. But it has been pointed out that this method leads to difficulties in some respects⁶⁾⁻⁹⁾. The way which overcomes the difficulties is to employ the more favorable methods, that is, the Laplace transform method first applied by Landau⁶⁾ or the stationary-wave method recently completed by Van Kampen⁹⁾. However the latter one applies only for a stationary or a decaying wave and does not for an excited wave which is growing exponentially with time. Therefore we shall adopt here the Laplace transform method by which we can without ambiguity get the dispersion relation for the problem considered.

In sections 2 and 3 will be preliminarily reviewed the fundamental equations and their solutions obtained by means of the usual technique of Laplace transform method. With a specified velocity distribution function which consists of one part for electrons in the main plasma and the other part for those in the beam, the dispersion relation in our case will be derived in section 4. Next will be discussed the excitation of plasma waves which build up exponentially in time. The characteristics of the plasma waves such as the frequency, the phase velocity and the time-rate of growth will be given as the wave number is varied. It will then be examined how much the wave characteristics change by taking into consideration of the thermal motion of electrons in the main plasma and by varying the ratio of the electron density in the beam to that in the main plasma. The effects of the velocity spread in the beam and the collisional damping will be discussed in sections 6 and 7. Finally in section 8 we shall consider the oscillations excited in a plasma layer bounded by ideally thin sheaths, which correspond more closely to practical cases.

§ 2. Fundamental Equations

The behaviors of electrons in a plasma can

be described by the distribution function of their velocities $f(v, \mathbf{x}, t)$ satisfying an integro-differential equation of Boltzmann type. Positive ions are simply assumed to be a uniform and continuous background of positive charges neutralizing the medium as a whole. In the absence of external fields, the Boltzmann equation can be written as*

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \frac{\partial f}{\partial \mathbf{x}} - \frac{e\mathbf{E}}{m} \cdot \frac{\partial f}{\partial \mathbf{v}} = \frac{\partial f}{\partial t} \Big|_{coll} \quad (2.1)$$

The term $\partial f / \partial t|_{coll}$ represents the instantaneous change of the distribution function arising from the binary close collisions. The electric field $\mathbf{E}$ is connected with the fluctuating charge concentrations of electrons by the Poisson equation. This field acts on an electron as a long-range force arising from the other electrons, as assumed by Vlasov¹⁰⁾. Then

$$\frac{\partial \mathbf{E}}{\partial \mathbf{x}} = \frac{e}{\epsilon_0} \left(n_0 - \int f d\mathbf{v} \right), \quad (2.2)$$

where n_0 is the density of the uniform positive background or the average density of electrons. Diving the distribution function into a stationary part $f_0(v)$ and a fluctuating part $f_1(v, \mathbf{x}, t)$, then

$$f(v, \mathbf{x}, t) = f_0(v) + f_1(v, \mathbf{x}, t). \quad (2.3)$$

The linearized equation for f_1 is obtained from Eq. (2.1) for small fluctuating components as usual,

$$\frac{\partial f_1}{\partial t} + \mathbf{v} \cdot \frac{\partial f_1}{\partial \mathbf{x}} - \frac{e\mathbf{E}}{m} \cdot \frac{\partial f_0}{\partial \mathbf{v}} = \frac{\partial f_1}{\partial t} \Big|_{coll}. \quad (2.4)$$

While the Poisson equation (2.2) becomes

$$\frac{\partial \mathbf{E}}{\partial \mathbf{x}} = - \frac{e}{\epsilon_0} \int f_1 d\mathbf{v}, \quad (2.5)$$

since $\int f_0(v) d\mathbf{v} = n_0$. In a low-pressure region,

short-range collisions play so little an important role that at present we neglect the collisional effect and in a later section we shall be back to this point.

We consider first the case where the plasma is extended to infinity and a spatial disturbance is given at an initial instance. Hence the fluctuating parts of the distribution function and the field intensity is conveniently represented by Fourier-analysis in space. Thus we can write

* We use the MKS rationalized unit throughout this paper.

$$\left. \begin{aligned} f_1(v, x, t) &= \iint_{-\infty}^{\infty} f_k(v, t) e^{ikx} dk, \\ E(x, t) &= \iint_{-\infty}^{\infty} E_k(t) e^{ikx} dk. \end{aligned} \right\} \quad (2.6)$$

Then fundamental equations (2.4) and (2.5) become for each component,

$$\left. \begin{aligned} \frac{\partial f_k}{\partial t} + ikvf_k - \frac{e}{m} E_k \frac{\partial f_0}{\partial v} &= 0, \\ ikE_k &= -\frac{e}{\epsilon_0} \int f_k(v, t) dv. \end{aligned} \right\} \quad (2.7)$$

These equations can be solved by means of Laplace transform method for a given initial condition. Each Fourier component and its time derivative are transformed by the following relations

$$\left. \begin{aligned} \int_0^{\infty} f_k(v, t) e^{i\omega t} dt &= F(v, k, \omega), \\ \int_0^{\infty} E_k(t) e^{i\omega t} dt &= \mathcal{E}(k, \omega), \end{aligned} \right\} \quad (2.8)$$

and

$$\int_0^{\infty} \frac{\partial f_k}{\partial t} e^{i\omega t} dt = -i\omega F(v, k, \omega) - f_k(v, 0). \quad (2.9)$$

While the inverse transformations are written as

$$\left. \begin{aligned} f_k(v, t) &= \frac{1}{2\pi} \int_{-\infty+i\gamma}^{\infty+i\gamma} F(v, k, \omega) e^{-i\omega t} d\omega, \\ E_k(t) &= \frac{1}{2\pi} \int_{-\infty+i\gamma}^{\infty+i\gamma} \mathcal{E}(k, \omega) e^{-i\omega t} d\omega, \end{aligned} \right\} \quad (2.10)$$

where the integration is carried out along a straight line parallel to the real ω -axis and lying onto the above of all the singularities of the integrands, $F(v, k, \omega)$ and $\mathcal{E}(k, \omega)$, so that γ is larger than some positive value of γ_a for which both

$$\int_0^{\infty} e^{-\gamma_a t} |f_k| dt$$

and

$$\int_0^{\infty} e^{-\gamma_a t} |E_k| dt$$

are bounded.

Then we obtain from Eq. (2.7)

$$\left. \begin{aligned} i(\omega - kv)F(v, k, \omega) + f_k(v, 0) \\ + \frac{e}{m} \mathcal{E}(k, \omega) \frac{\partial f_0}{\partial v} &= 0, \\ ik\mathcal{E}(k, \omega) &= -\frac{e}{\epsilon_0} \int F(v, k, \omega) dv. \end{aligned} \right\} \quad (2.11)$$

Here we take the wave vector of propagation k directed to the z -axis and assume the uniform distribution function f_0 to be an even function with respect to the velocity components perpendicular to z . These correspond essentially to the one-dimensional treatment, considering only the longitudinal fluctuations in the plasma. Putting $k_z = k$, $v_z = u$ and $\epsilon_z = \epsilon$, and integrating with respect to v_x and v_y in Eq. (2.11), we get

$$\begin{aligned} i(\omega - ku)G(u, k, \omega) + g(u, k, 0) \\ + \frac{e}{m} \mathcal{E}(k, \omega) \frac{dg_0}{du} = 0, \end{aligned} \quad (2.12)$$

$$ik\mathcal{E}(k, \omega) = -\frac{e}{\epsilon_0} \int_{-\infty}^{\infty} G(u, k, \omega) du, \quad (2.13)$$

where

$$\left. \begin{aligned} G(u, k, \omega) &= \iint_{-\infty}^{\infty} F(v, k, \omega) dv_x dv_y, \\ g(u, k, 0) &= \iint_{-\infty}^{\infty} f_k(v, 0) dv_x dv_y, \\ g_0(u) &= \iint_{-\infty}^{\infty} f_0(v) dv_x dv_y. \end{aligned} \right\} \quad (2.14)$$

§ 3. Solution by Laplace Transform Method

We shall solve the combined equations (2.12) and (2.13). Since both k and u are real and $Im(\omega) > 0$, $\omega - ku \neq 0$. Then Eq. (2.12) gives

$$\begin{aligned} G(u, k, \omega) &= \frac{i}{(\omega - ku)} \\ &\times \left[\frac{e}{m} \mathcal{E}(k, \omega) \frac{dg_0}{du} + g(u, k, 0) \right]. \end{aligned} \quad (3.1)$$

Inserting it into Eq. (2.13), we find for the Fourier-Laplace transform of the electric field component

$$\mathcal{E}(k, \omega) = \frac{e}{\epsilon_0 k^2} \frac{\int_{-\infty}^{\infty} \frac{g(u, k, 0)}{(u - \omega/k)} du}{\left[1 - \frac{e^2}{m\epsilon_0 k^2} \int_{-\infty}^{\infty} \frac{dg_0/du}{u - \omega/k} du \right]}. \quad (3.2)$$

Note that the above relation holds only in the region of $Im(\omega) > \gamma_a > 0$, where $E(k, \omega)$ is an analytic function of ω . However, to find $E(z, t)$ explicitly it is necessary to define $E(k, \omega)$ on the whole complex ω -plane, by means of an analytic continuation of the function. For a positive value of k , $Im(\omega/k)$ is

also positive. In this case, following Landau⁶⁾, the path of integration along the real axis in Eq. (3.2) with respect to velocity u can be modified on the complex u -plane to a path C in the lower half-plane such that we have no singularity of $g(u, k, 0)$ or dg_0/du either on C or between C and the real axis (Fig. 1(a)).

Fig. 1 (a) represents the contour of integration C on the complex u -plane for $k > 0$; (b) C' for $k < 0$.

It is easily shown that the integration thus defined with the contour C is always single-valued and analytic as the point ω/k crosses the real axis from the upper half u -plane and then moves into the lower half plane. Hence the integration defined above gives the analytic continuation over the whole region of ω -plane. Thus we can get, for $k > 0$,

$$\varepsilon(k, \omega) = \frac{e}{\varepsilon_0 k^2} \frac{\int_C \frac{g(u, k, 0)}{u - \omega/k} du}{\left[1 - \frac{e^2}{m \varepsilon_0 k^2} \int_C \frac{dg_0/du}{u - \omega/k} du \right]}. \tag{3.3}$$

For a negative value of k , $Im(\omega/k)$ becomes negative. Therefore the integrand in the integration on the u -plane has a singularity $u = \omega/k$ in the lower half plane. Hence according to the similar argument we must take a countour of integration C' deformed to the upper half plane as in Fig. 1(b) instead of the the contour C for the positive k . Then the analytical continuation over the whole plane yield the result for $k < 0$:

$$\varepsilon(k, \omega) = \frac{e}{\varepsilon_0 k^2} \frac{\int_{C'} \frac{g(u, k, 0)}{u - \omega/k} du}{\left[1 - \frac{e^2}{m \varepsilon_0 k^2} \int_{C'} \frac{dg_0/du}{u - \omega/k} du \right]}. \tag{3.4}$$

The electric field component $E(z, t)$ is obtained by means of the following inverse Laplace transformation

$$E(z, t) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty + i\gamma}^{\infty + i\gamma} E(k, \omega) e^{i(kz - \omega t)} dk d\omega. \tag{3.5}$$

Substituting the expressions (3.3) and (3.4) into the above relation, and integrating on the ω -plane, we get finally

$$E(z, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} dk \left[\sum_j C_j(k) e^{i(kz - \omega_j t)} + \sum_l D_l(k) e^{i(kz - \omega_l t)} \right], \tag{3.6}$$

where ω_j are the singular points of $g(\omega/k, k, 0)$, if any, in the lower half ω -plane, providing the decaying feature to the first term, while ω_l are the roots of the denominator of $E(k, \omega)$ and are determined by the dispersion relation as follows

$$D(k, \omega) = 1 - \frac{e^2}{m \varepsilon_0 k^2} \int_{C \text{ or } C'} \frac{dg_0/du}{u - \omega/k} du = 0. \tag{3.7}$$

The contour of integration C or C' corresponds to the positive or negative value of k , respectively.

§ 4. Dispersion Relation with Specified Distribution Functions

The dispersion relation $D(k, \omega) = 0$ gives the connection between ω and k for plasma waves; in our case ω is in general complex such as $\omega = \omega_0 + i\gamma$. Solving ω as a function of k , we have the frequency of the plasma wave $\omega_0(k)$ and the time rate of wave-growth or wave-decay $\gamma(k)$.

In this section we shall treat a case when an electron beam is injected into a uniform thermal plasma. The one-dimensional treatment allows us to regard the injected beam as the uniform flow parallel to the z direction in the region through which the beam really passes. Then the distribution function $g_0(u)$ is divided into two parts: $g_p(u)$ for the uniform plasma and $g_b(u)$ for the injected beam. Here $g_p(u)$ is considered as the Maxwellian form as below

$$\begin{aligned} g_p(u) &= n_p \left(\frac{m}{2\pi \kappa T} \right)^{1/2} e^{-mu^2/2\kappa T} \\ &= \frac{n_p}{\sqrt{\pi} u_T} e^{-(u/u_T)^2}, \end{aligned} \tag{4.1}$$

where n_p is the electron density in the plasma $u_T = (2\kappa T/m)^{1/2}$ and κ the Boltzmann constant. For the present $g_b(u)$ is simply specified with the extremely sharp velocity distribution of δ -functional form

$$g_b(u) = n_b \delta(u - u_b), \quad (4.2)$$

where n_b is the electron density in the beam and u_b the velocity of it. Here it is to be noted that in the derivation of dispersion relation in the last section, the distribution function $g_b(u)$ is assumed to be an analytic function over the whole complex u -plane. Therefore, if we take this form of $g_b(u)$, we have to return to Eq. (3.2), the denominator of which gives in the present case

$$1 - \frac{e^2}{m\epsilon_0 k^2} \left[\int_{-\infty}^{\infty} \frac{dg_b/du}{u - \omega/k} du + \frac{n_b}{(u_b - \omega/k)^2} \right].$$

Then the analytical continuation can be carried out in the same way as before. The contour of integration along the real u axis can be replaced by the contour C or C' . Thus we get the following dispersion relation instead of Eq. (3.7)

$$D(k, \omega) = 1 - \frac{e^2}{m\epsilon_0 k^2} \left[\int_C \text{or } \int_{C'} \frac{dg_b/du}{u - \omega/k} du + \frac{n_b}{(u_b - \omega/k)^2} \right] = 0. \quad (4.3)$$

The integration with the contour C has been obtained by several authors for the Maxwellian distribution¹¹⁾. The result is

$$\int_C \frac{dg_b/du}{u - \omega/k} du = -\frac{2n_b}{u_T^2} \times \left[1 + i\sqrt{\pi}\beta e^{-\beta^2} \{1 + \Phi(i\beta)\} \right]. \quad (4.4)$$

where $\beta = \omega/ku_T$ and $\Phi(x)$ is the error function of the form

$$\Phi(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt.$$

While the integration with the contour C' is obtained by reversing the direction of imaginary axis, as seen in Figs. 1(a) and 1(b). Thus one finds immediately

$$\int_{C'} \frac{dg_b/du}{u - \omega/k} du = -\frac{2n_b}{u_T^2} \times [1 - i\sqrt{\pi}\beta e^{-\beta^2} \{1 - \Phi(i\beta)\}]. \quad (4.5)$$

Taking Eqs. (4.4) and (4.5), we can write Eq. (4.3) as

$$D(k, \omega) = 1 + \left[2 \left(\frac{\omega_p}{ku_T} \right)^2 \{1 \pm i\sqrt{\pi}\beta e^{-\beta^2} [1 \pm \Phi(i\beta)]\} - \left(\frac{\omega_b}{ku_T} \right)^2 \frac{1}{(\xi - \beta)^2} \right] = 0, \quad (4.6)$$

(+sign for $k > 0$, -sign for $k < 0$)

where $\xi = u_b/u_T$, $\omega_p^2 = n_p e^2/m\epsilon_0$ and $\omega_b^2 = n_b e^2/m\epsilon_0$. Since the wave for $k < 0$ runs backward in the direction of electron beam, the dispersion relation for $k < 0$ is seen to be identical with that for $k > 0$ with the electron beam running backward. Actually the relation (4.6) may be written as follows

$$D(k, \omega) = 1 + \left[2\beta_p^2 \{1 + i\sqrt{\pi}\beta e^{-\beta^2} [1 + \Phi(i\beta)]\} - \frac{\beta_b^2}{(\xi \mp \beta)^2} \right] = 0, \quad (4.7)$$

with the abbreviation of

$$\beta_p = \omega_p/ku_T \text{ and } \beta_b = \omega_b/ku_T, \quad (4.8)$$

where the value of k is always positive and the minus or the plus sign of the last term corresponds respectively to the wave which travels forward or backward in the beam direction. Thus Eq. (4.7) represents the dispersion relation for growing, stationary or decaying waves according to $\text{Im}(\omega) \gtrless 0$ respectively.

§ 5. Excitation of Plasma Waves

As an electron beam passes through a stationary plasma, the interaction between the beam and the plasma may be considered as rather strong in the range that the phase velocity of plasma wave is very near the beam velocity. When the electrons in the beam are slightly faster than the wave phase velocity, they will deliver their energy to the plasma wave. Hence the growing-up of the wave will occur. On the contrary if the wave phase velocity is too small, the coupling with the beam will become very weak or negligible and the plasma waves will not grow up. Thus it might be reasonable that we consider only the case for forward waves, since backward waves are easily shown not to give any growing wave. Furthermore, when there exists only the thermal plasma with a Maxwellian distribution in the limit of the vanishing electron beam, it will be also shown that we have no growing wave.

To discuss the behaviors of excited plasma wave we shall now solve the dispersion relation for $\text{Im}(\omega) > 0$. Then we write the relation (4.7) for a forward wave as

$$D(k, \omega) = 1 + \beta_s^2 [A(\beta) - B(\beta)] = 0, \quad (5.1)$$

where $\beta_s^2 = \beta_p^2 + \beta_b^2$ and

$$A(\beta) = 2\sigma_p \{1 + i\sqrt{\pi}\beta e^{-\beta^2} [1 + \Phi(i\beta)]\}, \quad (5.2)$$

$$B(\beta) = \sigma_b / (\xi - \beta)^2, \quad (5.3)$$

with $\sigma_p=\beta_p^2/\beta_s^2=n_p/(n_p+n_b)$ and $\sigma_b=\beta_b^2/\beta_s^2=n_b/(n_p+n_b)$. Dividing the real and imaginary part of $A(\beta)$ and $B(\beta)$, we find

$$1+\beta_s^2(A_r-B_r)=0, \tag{5.4}$$

$$A_i-B_i=0. \tag{5.5}$$

Two equations (5.4) and (5.5) thus obtained may be solved to determine a pair of unknown parameters; the real and imaginary parts of β , β_r and β_i , or $\omega_0(k)$ and $\gamma(k)$.

In Eq. (5.2) A_i is always positive for $Im(\omega)>0$, and hence in the absence of beam we have no solution of Eq. (5.5). On the contrary, in the presence of beam B_i is also positive for forward waves and therefore we can get some solutions in Eq. (5.5), while for backward waves B_i becomes negative which implies that there is no solution. These are just what mentioned at the beginning of this section.

For $|\beta| \gg 1$, the usual asymptotic expansion of $\Phi(i\beta)$ can be used which results

$$A(\beta)=-\frac{\sigma_p}{\beta^2}\left(1+\frac{3}{2\beta^2}+\frac{15}{4\beta^4}+\cdots\right). \tag{5.6}$$

Hence we find from Eq. (5.1)

$$\frac{\beta^2}{\beta_s^2}=\sigma_p\left(1+\frac{3}{2\beta^2}+\frac{15}{4\beta^4}+\cdots\right)+\sigma_b\frac{\beta^2}{(\xi-\beta)^2}. \tag{5.7}$$

It seems rather complicated to solve the above relation directly as functions of a variable k . Accordingly for the sake of convenience we may express the real and imaginary part of Eq. (5.7) in terms of variables $\chi=(\xi/\beta_r)-1$ and $\varepsilon=(\beta_i/\beta_r)^2$. Then the real part can be written as follows

$$\left(\frac{\omega_0}{\omega_s}\right)=\sigma_p\frac{(1-\varepsilon)}{(1+\varepsilon)^2}[1+S(\chi,\varepsilon;\xi)]+\sigma_b\frac{(\chi^2-\varepsilon)}{(\chi^2+\varepsilon)^2}, \tag{5.8}$$

where

$$S(\chi,\varepsilon;\xi)=\frac{3(\chi+1)^2}{\xi^2}\left[\frac{1}{(1+\varepsilon)}\left\{2\left(\frac{1-\varepsilon}{1+\varepsilon}\right)-\left(\frac{1+\varepsilon}{1-\varepsilon}\right)\right\}+\frac{5(\chi+1)^2}{4\xi^2(1+\varepsilon)^2}\left\{4\left(\frac{1-\varepsilon}{1+\varepsilon}\right)^2-3\right\}\right] \tag{5.9}$$

and $\omega_s=(\omega_p^2+\omega_b^2)^{1/2}$ represents the plasma frequency corresponding to the total electron density (n_p+n_b) . While the imaginary part becomes for $\varepsilon>0$,

$$\left(\frac{\chi^2+\varepsilon}{1+\varepsilon}\right)^2[1+T(\chi,\varepsilon;\xi)]=\sigma\chi, \tag{5.10}$$

where

$$T(\chi,\varepsilon;\xi)=\frac{3(\chi+1)^2}{\xi^2}\left[\frac{(1-\varepsilon)}{(1+\varepsilon)^2}+\frac{5(\chi+1)^2}{4\xi^2(1+\varepsilon)^2}\left\{3-\frac{16\varepsilon}{(1+\varepsilon)^2}\right\}\right], \tag{5.11}$$

and $\sigma=\sigma_b/\sigma_p=n_b/n_p$. The functions $S(\chi,\varepsilon;\xi)$ and $T(\chi,\varepsilon;\xi)$ represent the effect due to the thermal motion of electrons in the main plasma.

To see the range that γ becomes positive, we look for the points for $\gamma\rightarrow 0$; that is, $\varepsilon\rightarrow 0$ or $(\omega_0/\omega_s)\rightarrow 0$, since $\gamma/\omega_s=\varepsilon^{1/2}(\omega_0/\omega_s)$. The case with negligible thermal effects can be simply treated. For $\varepsilon\rightarrow 0$, Eq. (5.10) yields real roots of χ ; $\chi\rightarrow 0$ and $\chi\rightarrow\sigma^{1/3}$. The root $\chi\rightarrow 0$ is excluded since it makes the right hand side of Eq. (5.8) negative. For $\chi\rightarrow\sigma^{1/3}$, we get $(\omega_0/\omega_s)\rightarrow [(1+\sigma^{1/3})/(1+\sigma)]^{1/2}$, $ku_b/\omega_s\rightarrow [(1+\sigma^{1/3})^3/(1+\sigma)]^{1/2}$ and $u_w/u_b\rightarrow (1+\sigma^{1/3})^{-1}$. From $(\omega_0/\omega_s)\rightarrow 0$ we find $\chi=\varepsilon\rightarrow\sigma$ and at this limiting point $k\rightarrow 0$ and $u_w/u_b\rightarrow (1+\sigma)^{-1}$. The maximum value of γ/ω_s lies in an intermediary region between these two limits. In the case with a finite thermal temperature, the limiting value will be more or less corrected. The circumstances described above will be shown in Figs. 2-4.

In Eq. (5.10) we can obtain numerically $\chi(\varepsilon;\xi,\sigma)$ with parameters ξ and σ , which, inserted into the right hand side of Eq. (5.8) yields ω_0/ω_s as a function of ε . From these the time rate of wave-growth γ/ω_s and the phase velocity of the wave $u_w/u_b=1/(1+\chi)$ is obtained against a variable ε . Then we can

Fig. 2. Effect of mean thermal velocity of electrons in the main plasma on wave characteristics; say, normalized frequency ω_0/ω_s , time-rate of wave-growth γ/ω_s and phase velocity u_w/u_b of excited plasma waves for $n_b/n_p=0.1$.

represent all the quantities as a function of ku_b/ω_s instead of ε . Thus we get finally Figs. 2-4.

In Fig. 2 the ratio of the electron density in the beam to that in the plasma is fixed, typically at 0.1. Then it can be regarded as representing the effect due to, on the one hand, the increase of the beam velocity u_b for a definite thermal velocity u_T and, on the other hand, the decrease of the thermal velocity in the main plasma for a definite beam velocity. The figure represents the wave characteristics in detail which for the fixed beam velocity u_b the time rate of wave-growth γ becomes positive in the range of wave number k between zero and some critical value and reaches its maximum in an intermediate value of k , as

Fig. 3. Wave characteristics for negligible thermal effects with values of ratio n_b/n_p equal to and less than one.

Fig. 4. Wave characteristics for negligible thermal effect with values of ratio n_b/n_p larger than one.

excited wave has a value a little below the beam velocity and decreases gradually from the maximum at $k=0$ to that at the critically mentioned previously. The phase velocity of value of k . Accordingly the frequency of oscillation increases almost linearly with k . For small value of ku_b/ω_s we have oscillations far below the main plasma frequency ω_p or the total plasma frequency ω_s , while for $ku_b/\omega_s \sim 1$ the coupling between the beam and the main plasma is greatest and γ has a maximum in this region. For $ku_b/\omega_s \gg 1$, there can be no growing wave; there remains only stationary or attenuating waves. These are just what has been discussed by Bohm and Gross qualitatively²⁾.

Fig. 3 shows the variations with the increase of the density in the beam from a small value to the value equal to the density in the main plasma with a negligible thermal velocity. As the beam density approaches to the plasma density, the phase velocity becomes slower until it takes a constant value independent of k or a half velocity of the beam for $n_b/n_p=1$. In the latter case the wave frequency is exactly proportional to k from zero to ω_s ; for a maximum γ , however, the frequency ω_0 is rather below the total plasma frequency ω_s and is very near the main plasma frequency ω_p . In Fig. 4 are shown, in a way similar to Fig. 3, the characteristics of growing waves for the case where the beam density is further increased beyond the plasma density. The characteristics in this region of density can be readily obtained from those for lower densities as seen in Fig. 3 in a following way.

In the case when the ratio of density σ has a value σ_1 less than one, as in Fig. 3, the dense main plasma is at rest and the beam running through it. Then we get for this system ω_0/ω_s , γ/ω_s and u_w/u_b as before. Next consider a system having the value of the ratio n_b/n_p equal to $1/\sigma_1$, larger than one. If we slide with the same velocity as that of the beam in this system, the electrons in the beam may be seen at rest and the electrons in the main plasma running to the reverse direction. Then we find the same system as before with the value of ratio σ_1 except the beam velocity reversed, so that the phase velocity becomes negative without change of ω_0 and γ . Hence, back to the original system, we can express the phase velocity and the wave frequency of

the system with the value of density ratio $1/\sigma_1$ as $1-(u_v/u_b)$ and $(\omega_0/\omega_s)(u_b-u_v)/u_v$, by the use of the value of (u_v/u_b) in the system with the value of ratio σ_1 . The characteristics for $\sigma=10$ and 100 in Fig. 4 are thus readily obtained from those for $\sigma=0.1$ and 0.01 in Fig. 3, respectively. From both Figs. 3 and 4 we see the following features by the variation of n_b/n_p ; the time rate of building-up in excited waves (normalized by ω_s) is greatest at $n_b/n_p=1$ and becomes smaller as the value of n_b/n_p deviates from 1, and its maximum for each case lies near the region of $ku_b/\omega_s \sim 1$. The phase velocity and the normalized oscillating frequency of waves still more decrease with the increase of the ratio n_b/n_p .

§ 6. Effects by Velocity Spread of Electron Beam

Thus far we have not taken into account of the velocity spread in the electron beam. An actual beam will have a velocity spread due to an initial distribution of electron and due to collisions or scatterings of electrons in the medium. Here we shall simply assume the approximate velocity distribution function of the form

$$g_b(u) = \begin{cases} n_b/2\delta & \text{for } u_b - \delta < u < u_b + \delta, \\ 0 & \text{otherwise.} \end{cases} \quad (6.1)$$

Then we get, instead of the term $B(\beta)$ in Eq. (5.1)

$$B_\delta(\beta) = \sigma_b/[(\xi - \beta)^2 - \eta^2] \quad (6.2)$$

with $\eta = \delta/u_T$. Thus Eqs. (5.8) and (5.10) are modified, resulting finally in the limit of negligible thermal effects in the main plasma

$$\left(\frac{\omega_0}{\omega_s}\right)^2 = \frac{1}{1+\sigma} \left[\frac{1-\varepsilon}{(1+\varepsilon)^2} + \sigma \frac{\chi^2 - (\varepsilon + \varphi)}{(\chi^2 + \varepsilon)^2 - 2(\chi^2 - \varepsilon)\varphi + \varphi^2} \right] \quad (6.3)$$

and

$$\frac{1}{(1+\varepsilon)^2} [(\chi^2 + \varepsilon)^2 - 2(\chi^2 - \varepsilon)\varphi + \varphi^2] = \sigma\chi, \quad (6.4)$$

where

$$\varphi = \eta^2/\beta r^2 = (\delta/u_b)^2(1+\chi)^2 = \mu(1+\chi)^2 \quad (6.5)$$

with $\mu = (\delta/u_b)^2$. Hence we have

$$\left(\frac{\omega_0}{\omega_s}\right)^2 = \frac{(1+\chi)}{(1+\sigma)(1+\varepsilon)^2} \left[\left(1 - \frac{\varepsilon}{\chi}\right) - \mu \frac{(1+\chi)}{\chi} \right]. \quad (6.6)$$

and

$$\frac{1}{(1+\varepsilon)^2} [(\chi^2 + \varepsilon)^2 - 2(\chi^2 - \varepsilon)\mu(1+\chi)^2 + \mu^2(1+\chi)^4] = \sigma\chi. \quad (6.7)$$

Fig. 5 represents the effect by the velocity spread obtained from Eqs. (6.6) and (6.7). It is seen that the height of γ/ω_s becomes lower with the increase of the beam spread and that the waves with lower frequency are cut off.

Fig. 5. Effect of velocity spread in the beam on wave characteristics for $n_b/n_p=0.1$.

§ 7. Effects of Collisional Damping

We have neglected the collisional term in the Boltzmann equation in section 2. This may be justified as a good approximation in the low pressure region where the mean free path of electrons is longer than or comparable with the dimension concerned. However, as the mean free path becomes comparatively shorter, the effect of collisions will not be disregarded. Now we shall be contented ourselves with a most simple treatment that $\partial f_1/\partial t|_{coll}$ is replaced by $-\gamma_o f_1$, since the more satisfactory treatment of this term would lead us to a rather complex formula. γ_o is the damping rate by collision and the inverse of the collisional relaxation time τ_o . Setting like this and putting $f_1 = \bar{f}_1(t) e^{-\gamma_o t}$ in Eq. (2.4), we then find that the function $\bar{f}_1(v, x, t)$ satisfies the same form of equation as Eq. (2.4) in the absence of the collisional term. Consequently using this form of $\bar{f}_1$, we can discuss the wave characteristics as before and obtain the time rate of wave increase $\gamma(k)$, which is just represented in Figs. 2-5. Thus all the oscillatory quantities have such a factor of $\exp[(\gamma - \gamma_o)t]$ that γ must be greater than γ_o in order to give rise to the building-up of oscillations. Therefore the collisional damping becomes more effective when there are some causes that suppress the height of γ . For

instance, the suppression of oscillations due to the velocity spread in the beam will be more considerable, when combined with the collisional effect.

§ 8. Oscillations in a Uniform Plasma Layer

Consider the case when the medium is bounded by sharply defined sheaths and hence the main plasma is contained within a uniform layer having a finite thickness. The boundary sheaths are ideally assumed to have an infinitesimal thickness, so that the thermal electrons in the plasma are all reflected without any loss of energy.

If we excite a growing wave by an electron beam traversing in this layer, we shall have a standing wave with nodes at both ends. A standing wave is decomposed into a forward wave, which propagates to the same direction as that of beam velocity, and a backward wave. According to the arguments in the previous section, the former will interact strongly with the electron beam when almost synchronized, while the latter will not. The forward component of the wave will be delivered the energy from the beam and the backward component will play a regenerative role by which the wave energy will return to the forward component.

In a layer with the thickness of D is contained an integer times a half wavelength of the standing wave, i.e., $D = n\lambda/2$ where n is an integer and λ the wavelength. Hence k has discrete values: $k = 2\pi/\lambda = n\pi/D$. These cases are also covered by Figs. 2-5. with the fixed values of k given above. Figs. 3-5 indicate that, as the beam velocity increases, γ starts from a small value, passing through a maximum and then decreases to zero, beyond which the beam is so faster than the wave that the net exchange of energy between them vanishes. It is interesting to note that, for a suitable value of D , there may be several oscillations with different values of k corresponding to the fundamental ($n=1$) and the harmonics ($n \leq 2$); but in frequency they are not exactly the harmonics.

§ 9. Discussions

In seeking the solutions of the dispersion relation we have employed an approximation such as $|\beta| \gg 1$, which means that the phase

velocity of the plasma wave u_w is much greater than the thermal velocity u_T in the main plasma. As seen in Figs. 2 and 3, the value of u_w/u_b is very near or at least of the same order of magnitude with one. In consequence, if $\xi = u_b/u_T$ is much larger than 1, so is the case for β , resulting a good approximation. In Fig. 2 the errors introduced are really small for $\xi^2 \geq 16$, but it will probably become a little larger for $\xi^2 = 8$, although we have not evaluated it. For a still lower value of ξ , the approximate expansion used does not give the reasonable result. Then the evaluation will have to be made by the use of a numerical table.

Since the whole treatment is based on the linearized theory, the range of validity of this work is restricted to an initial stage in which the plasma waves build up from the ground level. To find the intensity of excited plasma waves we must obtain the stationary amplitude of enhanced plasma waves, taking into account of the non-linear terms.

We have neglected the deceleration of electrons in the beam which is caused by the energy transfer to the plasma wave or by collisions with the particles in the main plasma. It corresponds to the circumstance that such an energy exchange is very small in the linearized theory.

In section 6 we considered the phenomenological spread of the beam velocity, which is due partly to the collisions in the medium and partly to the interaction with the growing plasma wave. It seems probable, in particular, that the latter interaction will be responsible for an abnormal scattering of the beam which has been pointed out by Langmuir¹²⁾ and others²⁾. This will also be related to the non-linear plasma wave.

We have not examined here the amplification of an traveling plasma wave, in the case of which the fundamental equations are Fourier-analysed in time and Laplace-transformed in space. The dispersion relation thus obtained by similar procedures as before is turned out to have the same expression as Eq. (4.7), where, on the contrary, ω is real and k is complex. Recently a corresponding experiment has successfully performed¹³⁾. In near future we shall present the results for this case in another place.

Acknowledgements

The author would like to thank Professor T. Kihara for his helpful remarks concerning this manuscript. He is also indebted to Professor S. Kojima and Dr. K. Takayama for their interest and valuable discussions.

Half-Shade Device for the Precise Measurement of the Principal Angle of Incidence

By Koreo KINOSITA and Sadao NOMURA

*Department of Physics and Chemistry,
Gakushuin University, Mejiro, Tokyo*

(Received September 6, 1958)

Pfund's half-shade analyzer, which originally was devised for the measurement of the Brewsterian angle, φ_B , can be applied to the measurement of the principal angle of incidence, φ_p . Its sensitivity, h , and possible sources of systematic errors are discussed. It is shown that, in the measurement of φ_B , h can be made to approach ∞ , but in the measurement of φ_p , h is finite and sometimes very small. A superior half-shade device for the precise determination of φ_p is proposed, which consists of a $\lambda/4$ -plate, a half-shade plate of the type of Bravais bi-plate, and an analyzer (polarizing plate). Its sensitivity is fully discussed and the systematic errors are analyzed. Experimental test of the new device is briefly described.

§ 1. Introduction

One of us pointed out several years ago¹⁾ that Pfund's half-shade method²⁾ for the accurate measurement of the Brewsterian angle can be applied to the measurement of the principal angle of incidence. The angle determined by Pfund's method, φ_P , will be equal to the Brewsterian angle of the sample φ_B if the surface of the sample is ideally well-defined. If there is a surface layer on the sample, as would be the case in most experi-

ments, φ_P will be equal to the *principal angle of incidence* φ_p , i.e. the angle of incidence at which one of the principal axes of the vibration ellipse of the reflected beam lies in the plane of incidence. We found¹⁾ that the Pfund angle φ_P of a clean glass surface did change when the humidity of the ambient atmosphere was varied, showing that φ_P , or φ_p , was influenced by the presence of an extremely thin layer of adsorbed water on the sample.

A systematic experiment was started to in-

investigate the thickness d and the refractive index n of this adsorbed water film as a function of the relative humidity. The specimen is illuminated with a parallel beam of linearly polarized light, and the reflected beam which is elliptically polarized is examined. The principal angle of incidence φ_p is determined by Pfund's method. According to Sissingh and Groosmuller's theory³⁾ the difference between φ_p and φ_B (the Brewsterian angle of the substrate), $\varphi' = \varphi_p - \varphi_B$, will, in combination with the ellipticity ρ of the reflected beam measured at the angle of incidence equal to φ_B , allow us to calculate both d and n . It was soon noticed, however, that the sensitivity of Pfund's method was unsatisfactory for this purpose.

It is true that measurement of any parameter* of the elliptical vibration other than φ_p may also serve for the evaluation of d and n ; but difficulties arising from the fact that the adsorbed film was extremely thin suggested that the above method was the most promising. So we entered into the investigation of a more sensitive half-shade method for the measurement of the principal angle of incidence.

Few workers have been engaged in this problem. Sissingh³⁾ seems to have succeeded in determining φ_p with a probable error of the order of 1' or less, but no detailed description of his method of measurement could be found in the literatures available to us. Pfund²⁾ also claimed a sensitivity of the same order in his measurement of the "Brewsterian angle."** In some of our measurements, however, we were unable to attain this sensitivity.

In § 2 of this paper, the characteristics, including the sensitivity, of Pfund's method will be fully discussed, and an explanation of the discrepancy between Pfund's claim and our experience will be given. In § 3, a new half-shade device suitable for the measurement of the principal angle of incidence will be described with a discussion on its sensitivity and systematic errors. In §§ 2 and 3, $(\partial\delta/\partial\varphi)_p$, i.e. the derivative at φ_p of the phase lag of the s-component behind the p-component, δ , with respect to the angle of incidence, φ ,

which appears in the expressions of sensitivity and systematic errors, is left as an unknown parameter. This will be evaluated in § 4. Experimentals will be described in § 5.

§ 2. Pfund's Method as a Method of Measurement of the Principal Angle of Incidence

a) Pfund's Method

If a parallel beam of linearly polarized light of azimuth α_0 is allowed to fall on the plane, quite well-defined surface (without any surface layer) of a transparent, isotropic medium, the reflected light restores linear polarization, but its azimuth α varies as a function of the angle of incidence φ :

$$\tan \alpha = \tan \alpha_0 \cdot \frac{r_s}{r_p} = -\tan \alpha_0 \frac{\cos(\varphi - \chi)}{\cos(\varphi + \chi)} \quad (1)$$

Here r_p and r_s denote the amplitude reflectivities of the two components vibrating parallel and perpendicular to the plane of incidence respectively, and χ the angle of refraction. All azimuths are measured from the plane of incidence (throughout this paper). If φ is increased passing through φ_B , the Brewsterian angle of the sample, α will change from an obtuse into an acute angle coinciding with $\pi/2$ at $\varphi = \varphi_B$ (Fig. 1). As is illustrated in Fig. 1, the change of α in the neighbour-

Fig. 1. Change of α as given by Eq. (1) vs. the angle of incidence φ . $\varphi_B = 56^\circ 38'$ ($n_2 = 1.5183$).

* This of course has to be independent of ρ .

** It is believed that at least some, not to say all, of his measurements gave φ_p instead of φ_B .

hood of $\pi/2$ can be much enhanced if α_0 is made small.

Pfund's method consists in exaggerating the change of α in this way and detecting its coincidence with $\pi/2$ very sensitively by the use of his half-shade analyzer. *Pfund's half-shade analyzer*, illustrated in Fig. 2, is similar in principle to the one employed by Chauvin⁴⁾ in improving the sensitivity of the Sénarmont compensator. A half-wave plate* is cut and cemented on the right half of a polarizing plate (Polaroid) so that the fast axis of the

Fig. 2. Pfund's half-shade analyzer.

former is parallel, and the transmission axis of the latter makes an angle of $\pi/4$, with respect to the line of demarcation. This analyzer is used with the half-wave plate away from the observer. The line of demarcation, or the fast axis of the half-wave plate, should be set exactly parallel to the plane of incidence. Now, if the light reflected from the sample be allowed to fall on the analyzer, it will be found, as a rule, that the "half-shade" reveals a large contrast. When $\varphi = \varphi_B$, or when $\alpha = \pi/2$, however, the two halves of the

analyzer will appear the same in brightness. Thus Pfund's method gives an accurate means of determining the Brewsterian angle.

This matching of brightness happens, as was remarked before¹⁾, not only when the light reflected from the sample is linearly polarized light of azimuth $\pi/2$, but also when it is elliptically polarized with one of its axes in the plane of incidence (See §2-c). Hence Pfund's method can also be applied to the measurement of the principal angle of incidence.

b) *The Brightness of the Two Halves of the Field*

Now we shall proceed to quantitative discussions of Pfund's method outlined above, with the aim of examining its ability as a method of measurement of the principal angle of incidence. For this, we shall adopt the Poincaré sphere representation⁵⁾.

In Pfund's original treatment, he assumed that

- I. The light reflected from the sample is linearly polarized.
- II. The birefringent plate is an exact half-wave plate with its axis exactly parallel to the plane of incidence.
- and
- III. The transmission axis of the polarizing plate makes an angle exactly equal to $\pi/4$ with the plane of incidence.

In place of these, our calculation will be based on the following generalized postulates.

I'. The reflected beam is elliptically polarized light represented by

$$E_p = A \exp i(\omega t + \delta) \quad \text{and} \quad E_s = B \exp i\omega t \quad (2)$$

where ω stands for the circular frequency of light. For the convenience of the discussion

Fig. 3. Parameters of the elliptical orbit of the reflected beam. $\rho = b/a$: ellipticity. ψ : azimuth of the ellipse.

* Pfund used a sheet of Cellophane.

c) *Conditions for the Matching of Brightness*

Pfund assumed that $\xi_1=0$, $\delta_1=\pi$ and $\sigma=\pi/4$, and that the light incident on the half-shade analyzer is linearly polarized ($\delta=0$). But in the following discussion inevitable errors in ξ_1 and δ_1 will be taken into account and an arbitrary value for σ assumed. If

$$\xi_1 = \Delta\xi_1 \quad \text{and} \quad \delta_1 = \pi + \Delta\delta_1 \quad (12)$$

where $\Delta\xi_1$ and $\Delta\delta_1$ are small quantities, the difference in brightness of the two halves will be

$$I = \sin 2\sigma \sin 2\alpha \cos \delta - 2\Delta\xi_1 (\sin 2\sigma \cos 2\alpha + \cos 2\sigma \sin 2\alpha \cos \delta) - \frac{1}{2}\Delta\delta_1 \sin 2\sigma \sin 2\alpha \sin \delta. \quad (13)$$

Case 1. $\delta=0$: When light reflected from the sample is linearly polarized ($\delta=0$), Eq. (13) becomes

$$I = \sin 2\sigma \sin 2\alpha - 2\Delta\xi_1 \sin 2(\sigma + \alpha) \quad (14)$$

showing that, if $\Delta\xi_1=0$, the two halves of the field will appear the same in brightness when

$$\alpha = 0, \quad \pm\pi/2, \quad \text{or} \quad \pi. \quad (15)$$

$\alpha=(\pm)\pi/2$ is realized when $\varphi=\varphi_B$. It is clear that, for the half-shade analyzer to be useful, σ may be given any value other than 0 and π . The best result is obtained when $\sigma=\pm\pi/4$, however, in which case $|\sin 2\sigma|$, and accordingly the contrast of the half-shade, reaches a maximum (See also § 2-d).

If there is a small error $\Delta\xi_1$ in the azimuth of the fast axis of the half-wave plate, the matching at $\alpha=\pi/2$ will be shifted to

$$\alpha = (\pi/2) + \Delta\alpha. \quad (16)$$

It can easily be shown that

$$\Delta\alpha = \Delta\xi_1, \quad (17)$$

if the second and the higher power terms in $\Delta\xi_1$ and $\Delta\alpha$ are neglected. But it would be preferable to represent the shift in terms of the angle of incidence. For this purpose, we calculate the derivative at $\varphi=\varphi_B$ of α , which is given by Eq. (1), with respect to φ . This is represented in terms of the refractive index n_2 of the sample (the substrate) as follows:

$$\left(\frac{\partial\alpha}{\partial\varphi}\right)_B = -\cot\alpha_0 \cdot \frac{(n_2^2+1)^2}{2n_2^3}. \quad (18)$$

Accordingly, the shift from φ_B of the angle of incidence at which the matching is observed is given by

$$\Delta\varphi = -\tan\alpha_0 \cdot \frac{2n_2^3}{(n_2^2+1)^2} \cdot \Delta\xi_1. \quad (19)$$

A small error in the phase lead of the half-wave plate, $\Delta\delta_1$, causes no error in the determination of φ_B .

Case 2. $\delta \neq 0$: If the light reflected from

the sample is elliptically polarized ($\delta \neq 0$), and $\Delta\xi_1 = \Delta\delta_1 = 0$, Eq. (13) becomes

$$I = \sin 2\sigma \sin 2\alpha \cos \delta, \quad (20)$$

showing that the difference in brightness of the two halves disappears when one of the following conditions is satisfied:

$$\delta = \pm\pi/2, \quad (21)$$

$$\alpha = 0, \quad \pm\pi/2, \quad \text{or} \quad \pi. \quad (22)$$

But Eq. (22) is to be discarded, because it is contradictory to the assumption that $\delta \neq 0$. Eq. (21) proves that the principal angle of incidence φ_p can be determined by Pfund's method. The sensitivity depends on σ and α .

If there are small errors in ξ_1 and δ_1 , the matching at $\delta=\pi/2$ will be shifted to

$$\delta = (\pi/2) + \Delta\delta. \quad (23)$$

Calculation neglecting the higher order terms shows that

$$\Delta\delta = -(2\Delta\xi_1 \cot 2\alpha + \frac{1}{2}\Delta\delta_1). \quad (24)$$

It is again preferable to represent the shift in terms of the angle of incidence. This can be written as

$$\Delta\varphi = \Delta\delta / (\partial\delta/\partial\varphi)_p, \quad (25)$$

but evaluation of $(\partial\delta/\partial\varphi)_p$, the derivative of δ with respect to φ at $\varphi=\varphi_p$, is accompanied by some complications. This will be discussed later (§ 4).

d) *Sensitivity*

In discussing the sensitivity, the errors $\Delta\xi_1$ and $\Delta\delta_1$ are insignificant and will be neglected.

Case 1. $\delta=0$: In this case, the matching in brightness is observed when $\alpha=\pi/2$, or when $\varphi=\varphi_B$. The intensity transmitted by the half-shade analyzer in this case is given by

$$J_1 = J_2 = \frac{1}{2}(1 - \cos 2\sigma) = J_B. \quad (26)$$

Now, if the angle of incidence is changed by a small amount, say $\Delta\varphi$, a contrast in brightness will arise, which is represented by

$$H = \left| \frac{J_1(\varphi_B + \Delta\varphi) - J_2(\varphi_B + \Delta\varphi)}{2J_B} \right| = \left| \frac{(\partial I / \partial \varphi)_B}{2J_B} \cdot \Delta\varphi \right|. \quad (27)$$

Substituting from Eqs. (14) into Eq. (27) and making use of the relations $\Delta\xi_1 = 0$ and $\partial I / \partial \varphi = \partial I / \partial \alpha \cdot \partial \alpha / \partial \varphi$, we get

$$H = \left| \frac{2 \sin 2\sigma}{1 - \cos 2\sigma} \cdot \left(\frac{\partial \alpha}{\partial \varphi} \right)_B \cdot \Delta\varphi \right| = h |\Delta\varphi|. \quad (28)$$

The coefficient

$$h = \left| \frac{2 \sin 2\sigma}{1 - \cos 2\sigma} \right| \cdot \left| \left(\frac{\partial \alpha}{\partial \varphi} \right)_B \right| \quad (29)$$

shall be called the *sensitivity* of the half-shade analyzer. In this expression, $(\partial \alpha / \partial \varphi)_B$ is independent of the characteristics of the analyzer and has been calculated in Eq. (18). $|2 \sin 2\sigma / (1 - \cos 2\sigma)|$ reaches a maximum when $\sigma = \pm\pi/4$ or $\pm 3\pi/4$, which is equal to 2. Hence the maximum sensitivity attainable is given by

$$h_{\max} = 2 \left| \left(\frac{\partial \alpha}{\partial \varphi} \right)_B \right| = 2 |\cot \alpha_0| \frac{(n_s^2 + 1)^2}{2n_s^3}. \quad (30)$$

Case 2. $\delta \approx 0$: If $\delta \approx 0$, the matching is observed when $\delta = \pi/2$, or when $\varphi = \varphi_p$. The intensity of light transmitted by the half-shade analyzer in this case is given by

$$J_1 = J_2 = \frac{1}{2}(1 + \cos 2\sigma \cos 2\alpha) = J_p. \quad (31)$$

The contrast in brightness which is revealed when $\varphi = \varphi_p + \Delta\varphi$ will be

$$H = \left| \frac{J_1(\varphi_p + \Delta\varphi) - J_2(\varphi_p + \Delta\varphi)}{2J_p} \right| = \left| \frac{\left(\frac{\partial I}{\partial \alpha} \right)_p \left(\frac{\partial \alpha}{\partial \varphi} \right)_p + \left(\frac{\partial I}{\partial \delta} \right)_p \left(\frac{\partial \delta}{\partial \varphi} \right)_p \cdot \Delta\varphi}{2J_p} \right|. \quad (32)$$

Substituting from Eq. (20) and Eq. (31) into Eq. (32), and making use of the relation that $\delta = \pi/2$ at φ_p , we get

$$H = h |\Delta\varphi|, \quad (33)$$

where

$$h = \left| \frac{\sin 2\sigma \sin 2\alpha}{1 + \cos 2\sigma \cos 2\alpha} \cdot \left(\frac{\partial \delta}{\partial \varphi} \right)_p \right| \quad (34)$$

represents the sensitivity. In this expression, α and $(\partial \delta / \partial \varphi)_p$ are independent of the characteristics of the half-shade analyzer. The maximum sensitivity is obtained when $\sigma = \pm\pi/4$ or $\pm 3\pi/4$ and* $\alpha = \pm\pi/4$ or $\pm 3\pi/4$, and is represented by

$$h_{\max} = |(\partial \delta / \partial \varphi)_p|. \quad (35)$$

* α can be varied through α_0 . See Eq. (3).

e) Discussion

Pfund's half-shade analyzer is an excellent device for the accurate determination of the Brewsterian angle φ_B . If the azimuth of the linearly polarized light incident on the sample, α_0 , is made small enough, the sensitivity will approach infinity (Eqs. (29), (30)), and, at the same time, the systematic error in the determination of φ_B due to the error in the azimuth of the half-wave plate will become negligibly small (Eq. (19)). There is a practical limit for the sensitivity, of course, because the intensity of light reflected from the sample approaches zero as α_0 approaches zero, but this is a character common to all sensitive half-shade devices.

In contrast, Pfund's analyzer is not very adequate for the determination of the principal angle of incidence φ_p . Firstly, a systematic error is hardly avoidable. The shift due to $\Delta\xi_1$ (Eq. (24)) can be cancelled by making α equal to $\pi/4$, which happens to be the condition for the maximum sensitivity; but there is no avoiding the shift due to $\Delta\delta_1$ but using an absolutely correct half-wave plate. Secondly, the sensitivity is rather poor. As was shown above, the maximum attainable sensitivity is equal to $|(\partial \delta / \partial \varphi)_p|$. If the sample be a piece of metal whose surface is ideally well-defined, $|(\partial \delta / \partial \varphi)_p|$ will be finite, as is shown by Fresnel's formulae. In case the sample be a transparent medium coated with a thin transparent film, this quantity will approach infinity only when nd , the optical thickness of the film, is *extremely* small; otherwise it will be finite and often rather small (See § 4).

Thus the discrepancy between Pfund's experience and our own is explained.

One of the conclusions of the discussions given above is that if one intends to measure the Brewsterian angle of a dielectric sample by Pfund's analyzer one should be extremely careful to avoid an alien film on its surface. Indeed, if the sample is kept in the unconditioned atmosphere, the water vapour will be adsorbed on it, and the measurement will give φ_p which is determined by the *composite surface* (the surface of the sample + the adsorbed film of water). The difference between φ_p and φ_B is small and could be neglected for most practical purposes, but the lowering of sensitivity might be serious.

§ 3. New Half-Shade Device

a) Description of the device

A new half-shade apparatus useful for the accurate determination of the principal angle of incidence was devised on the basis of the discussions given in § 2. It consists of a quarter-wave plate Q, a half-shade plate of the type of Bravais bi-plate H, and an analyzer (polarizing plate) A arranged in line as is illustrated in Fig. 5.

The fast axis of Q is set parallel to the

Fig. 5. New half-shade device for the determination of the principal angle of incidence. Q: quarter-wave plate. H: half-shade plate. A: analyzer (polarizing plate).

plane of incidence.

The half-shade plate H is prepared by cutting a uniform sheet of mica along a line which forms an angle of $\pi/4$ with the fast axis and cementing the two halves on to a sheet of glass, one half being turned over before it is cemented. Thus, if the azimuth of the fast axis of the right half is ξ_1 , that of the left half ξ_1' is equal to $\xi_1 + (\pi/2)$. As is evident from the method of preparation, the absolute values of the phase lead caused by passage through the two halves are identical. We shall denote it by δ_1 .

The transmission axis of A is set in an azimuth of σ . σ , as well as ξ_1 , is adjustable.

b) Principle

Let the beam reflected from the sample be elliptically polarized light as given by Eq. (2). The p - and s -component of the beam after passage through Q are given by

$$E_p = A \exp i\left(\omega t + \delta + \frac{\pi}{2}\right)$$

and

$$E_s = B \exp i\omega t$$

respectively. Hence, the intensity transmitted by the right half of the half-shade device, J_1 , can be obtained by substituting $\delta + (\pi/2)$ for δ in Eq. (10). If we substitute $\xi_1' = \xi_1 + (\pi/2)$ for ξ_1 in the expression of J_1 thus obtained, it will represent J_2 , the intensity transmitted by the left half. It can easily be shown that

$$\frac{J_1}{J_2} = \frac{1}{2} [1 + \cos 2(\sigma - \xi_1) (\cos 2\alpha \cos 2\xi_1 - \sin 2\alpha \sin 2\xi_1 \sin \delta) - \sin 2(\sigma - \xi_1) \sin 2\alpha \{(\cos 2\xi_1 \sin \delta + \cot 2\alpha \sin 2\xi_1) \cos \delta_1 \pm \cos \delta \sin \delta_1\}] \quad (36)$$

In the last term the positive sign is for J_1 and the negative for J_2 respectively.

The difference in brightness of the two halves I is given by

$$I = J_1 - J_2 = -\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 \cos \delta \quad (37)$$

Eq. (37) implies that the both halves will appear the same in brightness if $\delta = \pi/2$, or $\varphi = \varphi_p$, irrespective of the values of σ , α and ξ_1 .

Needless to say, the measurement will give the Brewsterian angle φ_B if $\delta = 0$, or if the beam reflected from the sample be linearly polarized

c) Sensitivity

The contrast in brightness of the two halves

of the field, H , which is to be observed when $\varphi = \varphi_p + \Delta\varphi$, where $\Delta\varphi$ is small, is given by Eq. (32). J_p , the transmitted intensity at $\varphi = \varphi_p$, is obtained by substituting $\pi/2$ for δ in Eq. (36):

$$J_p = \frac{1}{2} [1 + \cos 2(\sigma - \xi_1) \cos 2(\alpha + \xi_1) - \sin 2(\sigma - \xi_1) \sin 2(\alpha + \xi_1) \cos \delta_1] \quad (38)$$

Substitution from Eqs. (37) and (38) into Eq. (32) gives

$$H = h |\Delta\varphi|, \quad (39)$$

where

$$h = |\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 \times \{1 + \cos 2(\sigma - \xi_1) \cos 2(\alpha + \xi_1) - \sin 2(\sigma - \xi_1) \sin 2(\alpha + \xi_1) \cos \delta_1\}^{-1} \times (\partial\delta/\partial\varphi)_p| \quad (40)$$

represents the sensitivity of the half-shade device.

Here we have a free choice in the value of δ_1 ; σ and ξ_1 are adjustable parameters of the half-shade device; α also is adjustable through α_0 (See Eq. (3)). The most useful combination of the values of these parameters is found to be the following:

$$\delta_1 \approx \pi/2, \quad \sigma - \xi_1 \approx \pi/2 \quad \text{and} \quad \alpha + \sigma \approx \pi/2$$

Let us assume

$$\left. \begin{aligned} \delta_1 &= (\pi/2) + \Delta\delta_1, \\ \sigma - \xi_1 &= (\pi/2) + \varepsilon, \\ \alpha + \sigma &= (\pi/2) + \eta. \end{aligned} \right\} \quad (41)$$

Substitution into Eq. (40) yields

$$h = \left| \frac{\varepsilon \sin 2\alpha}{2\varepsilon^2 - 2\varepsilon\eta + \eta^2} \cdot \left(\frac{\partial \delta}{\partial \varphi} \right)_p \right|, \quad (42)$$

if we neglect the third powers of the small quantities $\Delta\delta_1$, ε and η . Eq. (42) implies that h tends to infinity if the half-shade plate is made of (approximate) quarter-wave plates, σ is set equal to $(\pi/2) - \alpha$, and ξ_1 is allowed to approach $(\sigma - \pi/2)$, or $-\alpha$. It is evident that the best value for α is $\pm\pi/4$.

In practice there is a limit for sensitivity, of course, because if $(\sigma - \xi_1)$ is exactly equal to $\pi/2$ the transmitted intensity J_p will be zero and the observation will be impossible. This point, together with the experimental procedures for realizing the conditions given above, will be discussed later (§ 5).

d) Error analysis

Possible sources of a shift $\Delta\varphi$ in the value of φ_p determined by means of this new half-shade device are:

- an error in the azimuth of Q: $\Delta\xi_Q$,
- an error in the phase lead of Q: $\Delta\delta_Q$,

and

an error in the orthogonality of the fast axes of the two halves of H: $\Delta\xi_1'$.

1°. *Shift due to $\Delta\xi_Q$.* If the azimuth of the quarter-wave plate be $\Delta\xi_Q$ instead of zero, the quarter-wave plate will be represented by point Q' on the equator of the Poincaré sphere distant by $2\Delta\xi_Q$ from the Greenwich meridian (Fig. 6). If we regard the vertical great circle crossing the equator at Q' as new zero longitude, α , δ , ξ_1 and σ will be α' , δ' , ξ_1' and σ' respectively, where*

$$\sin 2\alpha' = \sin 2\alpha \sin \delta / \sin \delta', \quad (43)$$

$$\cot \delta' = \frac{(\cos \delta \cos 2\Delta\xi_Q - \cot 2\alpha \sin 2\Delta\xi_Q)}{\sin \delta}, \quad (44)$$

$$2\xi_1' = 2(\xi_1 - \Delta\xi_Q), \quad (45)$$

and

$$2\sigma' = 2(\sigma - \Delta\xi_Q). \quad (46)$$

Substitution from the above equations into Eq. (37) gives

$$I = -\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 \times (\cos \delta \cos 2\Delta\xi_Q - \cot 2\alpha \sin 2\Delta\xi_Q). \quad (47)$$

Fig. 6. Illustrating the transformations Eq. (43)–Eq. (46).

Accordingly, if $\Delta\xi_Q$ is small enough, the matching in brightness of the two halves of the field will be observed when $\delta = (\pi/2) + \Delta\delta$ where

$$\Delta\delta = -2 \cot 2\alpha \cdot \Delta\xi_Q. \quad (48)$$

In terms of the angle of incidence, the matching will be observed at $\varphi_p + \Delta\varphi$ instead of φ_p , where

$$\Delta\varphi = \Delta\delta / \left(\frac{\partial \delta}{\partial \varphi} \right)_p = \left\{ -2 \cot 2\alpha / \left(\frac{\partial \delta}{\partial \varphi} \right)_p \right\} \Delta\xi_Q. \quad (49)$$

At $\alpha = \pm\pi/4$ (the best values for obtaining high sensitivity), $\cot 2\alpha = 0$, and $\Delta\xi_Q$ will cause no shift in the determination of φ_p in so far as $(\partial\delta/\partial\varphi)_p \neq 0$.

2°. *Shift due to $\Delta\delta_Q$.* If the phase lead of the quarter-wave plate be $(\pi/2) + \Delta\delta_Q$, the difference in brightness of the two halves, I , will become

$$I = -\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 (\cos \delta - \Delta\delta_Q \sin \delta). \quad (50)$$

* As for the derivation of Eq. (44), refer to Eq. (9).

Hence the matching will be observed when $\delta = (\pi/2) + \Delta\delta$, or $\varphi = \varphi_p + \Delta\varphi$, where

$$\Delta\delta = \Delta\delta_Q, \quad \Delta\varphi = \Delta\delta_Q / \left(\frac{\partial\delta}{\partial\varphi} \right)_p. \tag{51}$$

This systematic error can be eliminated by rotating the quarter-wave plate Q by $\pi/2$ and making the measurement over again. In the latter case,

$$I = \sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 (\cos \delta + \Delta\delta_Q \sin \delta), \tag{52}$$

and the matching will be observed when $\delta = (\pi/2) + \Delta\delta'$, or $\varphi = \varphi_p + \Delta\varphi'$, where

$$\begin{aligned} I = J_1 - J_2 = & -\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 \cos \delta \\ & - \Delta\xi_1' [(1 - \cos \delta_1) \{ \sin 2(\sigma - \xi_1) (\cos 2\alpha \cos 2\xi_1 - \sin 2\alpha \sin 2\xi_1 \sin \delta) \\ & - \cos 2(\sigma - \xi_1) (\cos 2\alpha \sin 2\xi_1 + \sin 2\alpha \cos 2\xi_1 \sin \delta) \} - \cos 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1 \cos \delta] \dots \end{aligned} \tag{55}$$

Thus the matching will be observed when $\delta = (\pi/2) + \Delta\delta$, or $\varphi = \varphi_p + \Delta\varphi$, where

$$\left. \begin{aligned} \Delta\delta &= \frac{\sin 2(\sigma - \alpha - 2\xi_1) (1 - \cos \delta_1)}{\sin 2(\sigma - \xi_1) \sin 2\alpha \sin \delta_1} \Delta\xi_1', \\ \Delta\varphi &= \Delta\delta / \left(\frac{\partial\delta}{\partial\varphi} \right)_p. \end{aligned} \right\} \tag{56}$$

But this systematic error can be eliminated again by rotating the half-shade plate by $\pi/2$, making another measurement, and taking the arithmetic mean of the angles of incidence at which the matching is observed before and after the rotation.

§ 4. On $(\partial\delta/\partial\varphi)_p$

We have left $(\partial\delta/\partial\varphi)_p$ as an unknown parameter in Eqs. (25), (34), (42), (49), (51), (53) and (56). As is evident from these equations, the numerical value of this derivative may have an important influence on sensitivity and possible systematic errors of the half-shade device concerned.

It is well-known that if the reflecting surface is a perfectly well-defined surface of a transparent medium, $(\partial\delta/\partial\varphi)_p$, or $(\partial\delta/\partial\varphi)_B$, is equal to infinity; and if it is a perfectly well-defined metallic surface, $(\partial\delta/\partial\varphi)_p$ is equal to a finite value determined by the refractive index and the absorption coefficient of the metal. But as for the surface of a transparent medium covered with a thin transparent film, the investigation of which aroused our interest in the present study, hardly any quantitative in-

$$\Delta\delta' = -\Delta\delta_Q, \quad \Delta\varphi' = -\Delta\delta_Q / \left(\frac{\partial\delta}{\partial\varphi} \right)_p. \tag{53}$$

Thus the arithmetic mean of the two readings of the angle of incidence at which the matching is observed before and after rotating Q will give the correct value of the principal angle of incidence.

3°. *Shift due to $\Delta\xi_1'$.* Another systematic error will arise if the fast axes of the both halves of the half-wave plate are not exactly perpendicular to each other. If we let

$$\xi_1' = \xi_1 + (\pi/2) + \Delta\xi_1', \tag{54}$$

the difference in brightness of the two halves, I, will be given by the following equation.

formations on $(\partial\delta/\partial\varphi)_p$ have been available. Detailed examination of the dependence of δ on φ in the last case implies some interesting problems*, but here we shall confine ourselves to an approximate evaluation of $(\partial\delta/\partial\varphi)_p$ for a number of typical cases, which is immediately needed. The calculation will be based on Drude's theory⁷⁾.

Fig. 7. Illustration for Eq. (57).

Let a parallel beam of linearly polarized light of azimuth α_0 fall on the composite surface as illustrated in Fig. 7. The dielectric constants of the ambient medium, the film (of thickness $d \ll \lambda$), and the substrate are assumed to be 1, $\varepsilon (=n^2)$, and $\varepsilon_2 (=n_2^2)$ respectively. The inward normal of the surface shall be taken as the z-axis. If we neglect the second and the higher order terms in d/λ , the ratio in amplitude of the p-component to the

* These will be fully discussed in another paper to be published in the near future.

s-component of the reflected beam is given by⁷⁾

$$\frac{R_p}{R_s} = \frac{E_p r_p}{E_s r_s} = -\cot \alpha_0 \frac{\cos(\varphi + \chi)}{\cos(\varphi - \chi)} \times \left(1 + i \frac{4\pi}{\lambda} \cdot \frac{\varepsilon_2}{1 - \varepsilon_2} \cdot \frac{\cos \varphi \sin^2 \varphi}{\sin^2 \varphi - \varepsilon_2 \cos^2 \varphi} \cdot \eta \right). \quad (57)$$

Here φ and χ denote the angle of incidence and the angle of refraction respectively, and

$$\eta = p - d(1 + \varepsilon_2) + q\varepsilon_2, \quad (58)$$

where

$$p = \int_1^2 \varepsilon dz \quad \text{and} \quad q = \int_1^2 \frac{1}{\varepsilon} dz. \quad (59)$$

The limits of the integrals are the upper (1) and the lower (2) boundaries of the film (See Fig. 7).

Now, if the angle of incidence is in the neighbourhood of φ_p , we can put

$$\varphi = \varphi_p + \Delta = \varphi_B + \Delta. \quad (\Delta \ll 1) \quad (60)$$

The last transformation is allowed because the difference between φ_p and φ_B is neglected in the Drude approximation. Substituting from Eq. (60) into Eq. (57), and using the relations that $\tan \varphi_B$ is equal to $\sqrt{\varepsilon_2}$ and that the ratio of the imaginary part to the real part of r_p/r_s is equal to $\tan \delta$, we obtain the following equation:

$$\tan \delta = \frac{a + b\Delta}{\Delta} \cdot \eta. \quad (61)$$

Here

$$a = \frac{2\pi}{\lambda} \frac{\varepsilon_2 \sqrt{\varepsilon_2}}{(1 - \varepsilon_2^2) \sqrt{1 + \varepsilon_2}}, \quad (62)$$

and

$$b = \frac{2\pi}{\lambda} \frac{\varepsilon_2(2 - \varepsilon_2)}{(1 - \varepsilon_2^2) \sqrt{1 + \varepsilon_2}}. \quad (63)$$

Differentiation of Eq. (61) with respect to φ , or Δ (it is evident that $\partial/\partial\varphi = \partial/\partial\Delta$), gives

$$\frac{\partial \delta}{\partial \varphi} = -\frac{1}{a + 2b\Delta} \cdot \frac{1}{\eta}. \quad (64)$$

Thus the approximate value of $(\partial\delta/\partial\varphi)_p$ is given by

$$\left(\frac{\partial \delta}{\partial \varphi} \right)_p = -\frac{1}{a\eta}. \quad (65)$$

If we apply the mean value theorem* to Eqs. (58) and (59), and put

* The mean values of ε as defined by $p = \bar{\varepsilon}d$ and $q = d/\bar{\varepsilon}$ are not necessarily identical. But we equate them, just as Drude⁷⁾ *et al.* did.

$$\eta = (\bar{\varepsilon} - \varepsilon_2)(\bar{\varepsilon} - 1)d/\bar{\varepsilon}, \quad (66)$$

Eq. (65) is rewritten as

$$\left(\frac{\partial \delta}{\partial \varphi} \right)_p = -\frac{A}{d} \quad (67)$$

where

$$A = \frac{\lambda}{2\pi} \frac{(1 - \varepsilon_2^2) \sqrt{1 + \varepsilon_2}}{\varepsilon_2 \sqrt{\varepsilon_2}} \frac{\bar{\varepsilon}}{(\bar{\varepsilon} - \varepsilon_2)(\bar{\varepsilon} - 1)}. \quad (68)$$

If $\bar{\varepsilon} = 1$, $\bar{\varepsilon} = \varepsilon_2$, or $d = 0$, i.e. if there is no film on the surface,

$$(\partial\delta/\partial\varphi)_p = \infty.$$

In this case, φ_p is reduced to φ_B , and this equation represents the well-known phase jump of the p -component at the Brewsterian angle.

Table I. Evaluation of $(\partial\delta/\partial\varphi)_p$. For 15461 Å.

1.00	1.33	1.70	$5.24 \times 10^3 \text{ Å}$
1.00	1.46	1.70	6.27×10^3
1.00	1.33	1.50	9.10×10^3
1.00	1.46	1.50	33.4×10^3

Fig. 8. $-(\partial\delta/\partial\varphi)_p$ vs. film thickness d . $\bar{n}$: mean refractive index of the film. n_2 : refractive index of the substrate.

The numerical evaluation of $(\partial\delta/\partial\varphi)_p$ given in Table I and Fig. 8 is based on Eqs. (67) and (68). It will be seen that $|(\partial\delta/\partial\varphi)_p|$ approaches infinity if nd ($\bar{n} = \sqrt{\bar{\varepsilon}}$) draws toward zero, but it decreases monotonously as nd increases. In case $|(\partial\delta/\partial\varphi)_p|$ is small, the sensitivity of Pfund's method as a method of measurement of φ_p is inevitably poor (Eq. (35)). In contrast, the sensitivity of the new method can be made to approach infinity by means of the procedures described in § 3-c, even when $|(\partial\delta/\partial\varphi)_p|$ is very small.

§ 5. Experimentals

A half-shade device of the type described in § 3 was mounted on a polarizing spectrometer* recently constructed in this laboratory, and was put to a series of experimental tests.

The optical system is schematically illustrated in Fig. 9. P: the polarizer (Polaroid), Q: the quarter-wave plate** of mica, H: the half-shade plate prepared according to the description given in § 3, and A: the analyzer (Polaroid), are so arranged that each can be independently rotated about the optical axis.

Fig. 9. Polarization spectrometer. S: light source (ultra-high pressure Hg-lamp). F: interference filter for monochromatization. P: polarizer. Q: quarter-wave plate. A: analyzer. L: viewing lens.

The errors of the quarter-wave plate and the half-shade plate we employed, as expressed in terms of $\Delta\delta_q$, $\Delta\delta_1$ and $\Delta\xi_1'$, were as follows:

$$\begin{aligned}\Delta\delta_q &= +2^\circ 53' \pm 10', \\ \Delta\delta_1 &= +2^\circ 10' \pm 10', \\ \Delta\xi_1' &= \pm(1^\circ 02' \pm 1').\end{aligned}$$

* This is equipped with an air-tight sample chamber convenient for the study of adsorption. The sample is held horizontally, and the collimator as well as the telescope-arm can be rotated in a vertical plane by means of a pantagraph mechanism. Details of this instrument will be described elsewhere.

** For λ 5461 Å.

These values, in combination with the numerical value of $(\partial\delta/\partial\varphi)_p$ which can be read from Fig. 8, will allow us to estimate the order of magnitude of the shift (or the systematic error) $\Delta\varphi$ inevitably introduced in a single measurement of φ_p . It will be seen that $\Delta\varphi$ may sometimes amount to several minutes of arc or more, but this is by no means serious because we can eliminate it easily by an appropriate combination of measurements, as was described in § 3-d.

The following arrangements are to be made prior to the measurement of the principal angle of incidence.

1°. The reflecting surface of the sample is set exactly horizontal (perpendicular to the plane of incidence).

2°. The fast axis of Q is set parallel to the plane of incidence as exactly as possible ($\xi_q=0$).

3°. The transmission axis of A is carefully set so that it makes an angle of $\pi/4$ with the plane of incidence ($\sigma=\pi/4$).

4°. The fast axis of the right half of H is so set that it makes an angle approximately (but not exactly) equal to $-\pi/4$ with the plane of incidence ($\xi_1 \approx -\pi/4$).

5°. The azimuth of the transmission axis of P is temporarily fixed at an arbitrary value between zero and $\pi/4$ ($0 < \alpha_0 < \pi/4$).

Now, if the half-shade device is viewed through L (Fig. 9), the both halves of the field

will in general reveal a remarkable contrast; on changing the angle of incidence, however, one will be able to find out an angle of incidence where the both halves appear the same in brightness—the principal angle of incidence φ_p . In this stage, however, one could determine φ_p only with an allowance of say scores of minutes or more. Thereupon one turns P, the polarizer, in order to let α approach toward $\pi/4$. The residual, invisible contrast will be enhanced by this operation, and when it is most exaggerated, α ($=\tan^{-1} B/A$. See Eq. (3)) will be equal to $\pi/4$. This is the condition for maximizing the sensitivity on the one hand and minimizing

the systematic error due to $\Delta\xi_0$ on the other. If this is accomplished, the half-shade device will work pretty satisfactorily, but the sensitivity can be improved still further by rotating H, the half-shade plate, so that ξ_1 approaches toward $-\pi/4$. As was pointed out before, this operation is accompanied by darkening of the field, and if ξ_1 is exactly equal to $-\pi/4$ the entire field will appear completely dark, but the sensitivity of the half-shade device will be sufficiently increased before the field becomes too dark. Thus the principal angle of incidence φ_p can be determined with a probable error less than $1'$.

We have to repeat the measurement over again after rotating the quarter-wave plate, and the half-shade plate, in order to eliminate the systematic errors due to $\Delta\delta_0$ and $\Delta\xi_1'$ respectively, but no further details will have to be described here.

The excellent sensitivity of the new device was confirmed in our measurements of φ_p on newly polished surfaces of optical glasses kept in extremely desiccated atmosphere. But in these measurements Pfund's half-shade analyzer was found to work equally well. In either case, the measurements carried out independently by two observers agreed within $1'$. This is only natural if one considers that in these measurements the surface layers must have been extremely thin, because in that case $|(\partial\delta/\partial\varphi)_p|$ approaches infinity (Fig. 8), and accordingly the sensitivity of Pfund's method will be very great (Eq. (35)).

In the measurements on *aged* polished surfaces of optical glasses, the new device proved

to work as well as before, while Pfund's analyzer failed to determine φ_p within 1° .

These data will be published, in the near future, in a paper on some optical investigations of the adsorption of water vapour on polished glass surfaces, in which this new method is being employed.

On the Theory of Fluids

By Kazuo HIROIKE

*Department of Physics, Tokyo Institute of Technology,
Oh-Okayama, Meguro, Tokyo*

(Received August 7, 1958)

The "netted ring approximation" is proposed. Several thermodynamic properties are derived by means of this approximation. The radial distribution function is also derived, the expression of which is similar to one based on the netted chain approximation of Rushbrooke and Scoins. The possibility of a phase change in the gas of hard spheres is pointed out.

§ 1. Introduction

In a paper with the same title as ours, Rushbrooke and Scoins¹⁾ have related the theory of fluids based on the radial distribution function to the direct correlation function of scattering theory. They have shown that the second approximation to the direct correlation function is related to the netted chain approximation to the radial distribution function. The netted chain approximation is as follows: The radial distribution function can be expressed as a power series in density. In order to obtain an approximate radial distribution function, Montroll and Mayer²⁾ have collected particular terms from the series and arranged in a closed form. The approximation adopted by them has been called the simple chain approximation by Rushbrooke³⁾, which has been shown to give the same result as Green's linear theory.^{4),5)} Rushbrooke and Scoins¹⁾ have taken account of some terms omitted by Montroll and Mayer. This is called the netted chain approximation.

Rushbrooke and Scoins¹⁾ have argued that their theory effects a considerable improvement on earlier theories. It has been, however, pointed out by us⁶⁾ that their theory fails to derive the Helmholtz free energy in a consistent way. In the present paper we shall eliminate this failing without changing the essential feature of their theory. Our method, which will be presented in the following section, is similar to one of Montroll and Mayer or Rushbrooke and Scoins, but is different from it in starting with the density expansion of the Helmholtz free energy instead of the radial distribution function.*

Our approximation will be called the "netted ring approximation."

Although in the present paper we are concerned with the equilibrium theory of classical fluids, the mathematical process similar to ours, that is, the process of collecting particular terms from a series, has been adopted by several authors in other fields of research. Among them Montroll and Ward⁷⁾ have generalized the simple chain approximation to the case of quantum statistics and have shown that in the case of the electron gas the classical limit of the approximation leads to the Debye-Hückel theory** while the low temperature limit leads to the Gell-Mann-Brueckner equation for the correlation energy of the ground state. The netted ring approximation adopted by us may be able to find its quantum statistical counterpart in the formulation of Montroll and Ward, though such an attempt will not be made in the present paper.

§ 2. Netted Ring Approximation

We shall consider a classical fluid of volume V and temperature T composed of N interacting molecules. The interaction energy will be assumed to be written as a sum of terms, each depending only on the distance apart r_{ij} of two molecules i and j , namely

$$\sum_{N \leq i < j \leq N} \phi(r_{ij}).$$

In such a case, the Helmholtz free energy A can be given by the well known expression⁹⁾

$$\frac{A}{NkT} = \log \left(\frac{h^3}{2\pi mkT} \right)^{3/2} \frac{\rho}{e} - \sum_{n=1}^{\infty} \frac{1}{n+1} \beta_n \rho^n, \quad (1)$$

** Ono⁸⁾ has also shown that in the case of electrolytes Green's linear theory, which is equivalent to the classical simple chain theory, leads to the Debye-Hückel theory.

* A general theory on this line is being constructed by Abe and Morita.

where ρ is the number density N/V , k the Boltzmann constant and h the Planck constant. The irreducible integrals β_n 's are defined by

$$\beta_n = \frac{1}{n! V} \iint \cdots \int \sum_{n+1 \geq i > j \geq 1} \prod \alpha_{ij} d\mathbf{r}_1 d\mathbf{r}_2 \cdots d\mathbf{r}_{n+1}, \quad (2)$$

All products which are more than singly connected.

where

$$\alpha_{ij} = \alpha(r_{ij}) = \exp(-\phi(r_{ij})/kT) - 1 \quad (3)$$

The integral β_n is a sum of integrals of various types as can be seen from Eq. (2).

Fig. 1.

By the "netted ring approximation" we will mean that we consider only the netted ring integrals, the integrands of which are illustrated by Fig. 1. In Fig. 1 $n+1$ molecules are represented by numbered circles and a factor α_{ij} occurring in the integrand under consideration is represented by a line drawn between two circles i and j . For brevity the function α_{ij} will be called the interaction between molecules i and j . The integral illustrated by Fig. 1 can be transformed as follows. Firstly we shall integrate over molecule i_1 . Because of the fact

$$\begin{aligned} & \int \alpha(r_{2,i_1}) \alpha(r_{1,i_1}) d\mathbf{r}_{i_1} \\ &= \int \beta^2(u) \exp(i\mathbf{u} \cdot \mathbf{r}_{23}) du \equiv a(r_{23}),^* \end{aligned} \quad (4)$$

where

$$\beta(u) = \frac{1}{(2\pi)^{3/2}} \int \alpha(r) \exp(-i\mathbf{u} \cdot \mathbf{r}) d\mathbf{r},^* \quad (5)$$

the integration over molecule i_1 leads to the effect that the interaction between molecules

* The definition of $a(r)$, $\beta(u)$ and $\gamma(u)$, denoted by Eqs. (4), (5) and (7) respectively, is equivalent to one given in reference 6. It is also equivalent to the definition given in reference 1 except for $\gamma(u)$, where the function $\gamma(u)$ differs from ours by a factor $(2\pi)^{3/2}$.

2 and 3 is changed from $\alpha(r_{23})$ into $\alpha(r_{23})\alpha(r_{23})$. The integration over molecules i_2 leads to the similar effect, and so forth. Thus the integration over molecules $i_1, i_2, \dots$, and i_k changes Fig. 1 into Fig. 2, where a double line shows that the interaction between two molecules is given by $\alpha(r)\alpha(r)$ and a single line means $\alpha(r)$ as in Fig. 1. In Fig. 2 there are $(n+1-2k)$ single lines and k double lines. The integration over molecules 1, 2, $\dots$, and $n+1-k$ can be carried out with the help of Fourier transform. Lastly the netted ring integral illustrated by Fig. 1 is written as

$$V(2\pi)^{3/2} (n-1) \int \{\beta(u)\}^{n+1-2k} \{\gamma(u)\}^k du, \quad (6)$$

where

$$\gamma(u) = \frac{1}{(2\pi)^3} \int \alpha(r) a(r) \exp(-i\mathbf{u} \cdot \mathbf{r}) d\mathbf{r}.^* \quad (7)$$

Let $N_n^{(k)}$ be the number of netted ring integrals considered above in β_n . The number of different ways in which k molecules may be selected from $n+1$ molecules, irrespective of the order of choice, is $(n+1)!/k!(n+1-k)!$.

Fig. 2.

The number of different ways in which $n+1-k$ molecules may be placed in a ring is $(n-k)!/2$. The number of different ways in which k molecules may be placed in $n+1-k$ positions is $(n+1-k)!/(n+1-2k)!$. Hence

$$\begin{aligned} N_n^{(k)} &= \frac{(n+1)!}{k!(n+1-k)!} \times \frac{(n-k)!}{2} \times \frac{(n+1-k)!}{(n+1-2k)!} \\ &= \frac{(n+1)!}{2} \frac{{}_n C_k}{n+1-k}, \end{aligned} \quad (8)$$

where ${}_n C_k$ is the number of combinations in which k objects may be selected from n distinguishable objects, namely

$${}_n C_k = \frac{n!}{k!(n-k)!}.$$

The integer k cannot be larger than $n+1-k$, that is,

$$k \leq \frac{n+1}{2}.$$

Putting Eqs. (6) and (8) together, we shall obtain as a contribution $\beta_n^{(n,r)}$ of the netted ring integrals to β_n

$$\beta_n^{(n,r)} = \int du (2\pi)^{3/2 \cdot (n-1)} \sum_{k=0}^{k \leq (n+1)/2} \frac{1}{2} \frac{n+1}{n-k+1} {}^{n-k+1}C_k \{\beta(u)\}^{n+1-2k} \{\gamma(u)\}^k \quad \text{for } n \geq 4. \quad (9)$$

The above consideration cannot be applied for $n \leq 3$. And so we shall put for $n \leq 3$

$$\left. \begin{aligned} \beta_3^{(n,r)} &= \int du \left[\frac{1}{2} (2\pi)^4 \{\beta(u)\}^4 + (2\pi)^4 \gamma(u) \{\beta(u)\}^2 \right], \\ \beta_2^{(n,r)} &= \beta_2 = \int du \left[\frac{1}{2} (2\pi)^{3/2} \{\beta(u)\}^3 \right], \\ \text{and} \quad \beta_1^{(n,r)} &= \beta_1 = (2\pi)^{3/2} \beta(0). \end{aligned} \right\} \quad (9')$$

A straightforward calculation leads to

$$\begin{aligned} \sum_{n=1}^{\infty} \beta_n^{(n,r)} \rho^n &= \bar{\rho} \beta(0) + \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left[\frac{1}{2} \frac{\bar{\rho} \beta(u) + 2\bar{\rho}^2 \gamma(u)}{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)} - \frac{1}{2} \bar{\rho} \beta(u) \right. \\ &\quad \left. - \frac{1}{2} \bar{\rho}^2 \beta^2(u) - \bar{\rho}^2 \gamma(u) - \frac{3}{2} \bar{\rho}^3 \beta(u) \gamma(u) - \bar{\rho}^4 \beta^2(u) \gamma(u) - \bar{\rho}^4 \gamma^2(u) \right], \end{aligned} \quad (10)$$

where

$$\bar{\rho} = (2\pi)^{3/2} \rho. \quad (11)$$

With the help of

$$\sum_{n=1}^{\infty} \frac{1}{n+1} \beta_n^{(n,r)} \rho^n = \frac{1}{\bar{\rho}} \int_0^{\bar{\rho}} \left[\sum_{n=1}^{\infty} \beta_n^{(n,r)} \rho^n \right] d\bar{\rho},$$

the Helmholtz free energy $A^{(n,r)}$ in the netted ring approximation is obtained as follows:

$$\begin{aligned} \frac{A^{(n,r)}}{NkT} &= \log \left(\frac{h^2}{2\pi mkT} \right)^{3/2} \frac{\rho}{e} - \frac{1}{2} \bar{\rho} \beta(0) + \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left[\frac{1}{2} \log \{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)\} \right. \\ &\quad \left. + \frac{1}{2} \bar{\rho} \beta(u) + \frac{1}{4} \bar{\rho}^2 \beta^2(u) + \frac{1}{2} \bar{\rho}^2 \gamma(u) + \frac{1}{2} \bar{\rho}^3 \beta(u) \gamma(u) + \frac{1}{4} \bar{\rho}^4 \beta^2(u) \gamma(u) + \frac{1}{4} \bar{\rho}^4 \gamma^2(u) \right]. \end{aligned} \quad (12)$$

§ 3. Several Thermodynamic Quantities and Radial Distribution Function

From Eq. (12), by means of the usual thermodynamic relations, all the other thermodynamic properties of the system may be derived. We shall give the expressions for the pressure p , the internal energy E and the chemical potential μ in the following. Hereafter we shall drop the superscript letter (n,r) which means the netted ring approximation.

$$\begin{aligned} \frac{p}{\rho kT} &= 1 - \frac{1}{2} \bar{\rho} \beta(0) + \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left[-\frac{1}{2} \log \{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)\} - \frac{1}{2} \frac{\bar{\rho} \beta(u) + 2\bar{\rho}^2 \gamma(u)}{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)} \right. \\ &\quad \left. + \frac{1}{4} \bar{\rho}^2 \beta^2(u) + \frac{1}{2} \bar{\rho}^2 \gamma(u) + \bar{\rho}^3 \beta(u) \gamma(u) + \frac{3}{4} \bar{\rho}^4 \beta^2(u) \gamma(u) + \frac{3}{4} \bar{\rho}^4 \gamma^2(u) \right]. \end{aligned} \quad (13)$$

$$\begin{aligned} \frac{E}{NkT} &= \frac{3}{2} + \frac{1}{2} \bar{\rho} T \frac{\partial \beta(0)}{\partial T} + \frac{1}{2} \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \frac{\{\bar{\rho} \beta(u) + \bar{\rho}^2 \gamma(u)\}^2}{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)} T \frac{\partial}{\partial T} \{\bar{\rho} \beta(u) + \bar{\rho}^2 \gamma(u)\} \\ &\quad - \frac{1}{4} \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du T \frac{\partial}{\partial T} \{\bar{\rho}^4 \beta^2(u) \gamma(u)\}. \end{aligned} \quad (14)$$

$$\frac{\mu}{kT} = \log \left(\frac{h^3}{2\pi m kT} \right)^{3/2} \rho - \bar{\rho} \beta(0) + \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left[-\frac{1}{2} \frac{\bar{\rho} \beta(u) + 2\bar{\rho}^2 \gamma(u)}{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)} \right. \\ \left. + \frac{1}{2} \bar{\rho} \beta(u) + \frac{1}{2} \bar{\rho}^2 \beta^2(u) + \bar{\rho}^2 \gamma(u) + \frac{3}{2} \bar{\rho}^3 \beta(u) \gamma(u) + \bar{\rho}^4 \beta^2(u) \gamma(u) + \bar{\rho}^4 \gamma^2(u) \right]. \quad (15)$$

It has been proved¹⁰⁾ that the radial distribution function $g(r)$ is related to the Helmholtz free energy A by

$$g(r) = \frac{2V}{N^2} \left(\frac{\delta A}{\delta \phi} \right)_r, \quad (16)$$

where $(\delta A / \delta \phi)_r$ is defined as follows. When the interaction potential ϕ is varied by $\Delta\phi$, the corresponding first order variation, with respect to $\Delta\phi$, of A is denoted by $F[\Delta\phi(r')]$, which is a linear functional of $\Delta\phi$. Then

$$\left(\frac{\delta A}{\delta \phi} \right)_r = F[\delta(r-r')].$$

The above definition is generalized to quantities other than the Helmholtz free energy. Relation (16) will be used for the calculation of $g(r)$ from Eq. (12), which gives the following expression for $g(r)$

$$g(r) = \frac{kT}{\rho} \left[-\bar{\rho} \left(\frac{\delta \beta(0)}{\delta \phi} \right)_r - \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \frac{\{\bar{\rho} \beta(u) + \bar{\rho}^2 \gamma(u)\}^2}{1 - \bar{\rho} \beta(u) - \bar{\rho}^2 \gamma(u)} \left\{ \bar{\rho} \left(\frac{\delta \beta(u)}{\delta \phi} \right)_r + \bar{\rho}^2 \left(\frac{\delta \gamma(u)}{\delta \phi} \right)_r \right\} \right. \\ \left. + \frac{1}{2} \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left\{ 2\bar{\rho}^4 \beta(u) \gamma(u) \left(\frac{\delta \beta(u)}{\delta \phi} \right)_r + \bar{\rho}^4 \beta^2(u) \left(\frac{\delta \gamma(u)}{\delta \phi} \right)_r \right\} \right]. \quad (17)$$

By the definition of $(\delta / \delta \phi)_r$ -operation we shall obtain

$$\left(\frac{\delta \alpha(r')}{\delta \phi} \right)_r = -\frac{1}{kT} \exp(-\phi(r)/kT) \delta(r-r')$$

and hence

$$\left(\frac{\delta \beta(u)}{\delta \phi} \right)_r = \frac{1}{(2\pi)^{3/2}} \int d\mathbf{r}' \left(\frac{\delta \alpha(r')}{\delta \phi} \right)_r \exp(-i\mathbf{u}\mathbf{r}') = -\frac{1}{(2\pi)^{3/2}} \frac{\exp(-\phi(r)/kT)}{kT} \exp(-i\mathbf{u}\mathbf{r}), \\ \left(\frac{\delta \alpha(r')}{\delta \phi} \right)_r = 2 \int du \beta(u) \left(\frac{\delta \beta(u)}{\delta \phi} \right)_r \exp(i\mathbf{u}\mathbf{r}') = -\frac{2}{(2\pi)^{3/2}} \frac{\exp(-\phi(r)/kT)}{kT} \int du \beta(u) \exp(i\mathbf{u}(\mathbf{r}' - \mathbf{r})), \\ \left(\frac{\delta \gamma(u)}{\delta \phi} \right)_r = \frac{1}{(2\pi)^3} \int d\mathbf{r}' \left[\left(\frac{\delta \alpha(r')}{\delta \phi} \right)_r a(r') + \alpha(r') \left(\frac{\delta a(r')}{\delta \phi} \right)_r \right] \exp(-i\mathbf{u}\mathbf{r}') \\ = -\frac{1}{(2\pi)^{3/2}} \frac{\exp(-\phi(r)/kT)}{kT} \left[\frac{1}{(2\pi)^{3/2}} a(r) \exp(-i\mathbf{u}\mathbf{r}) \right. \\ \left. + \frac{2}{(2\pi)^3} \iint du' d\mathbf{r}' \beta(u') \alpha(r') \exp(i\mathbf{u}'\mathbf{r}' - i\mathbf{u}'\mathbf{r} - i\mathbf{u}\mathbf{r}') \right].$$

The use of the above equations in Eq. (17) gives

$$g(r) = \exp(-\phi(r)/kT) \left[1 + \{1 + \rho a(r)\} f_0(r) + 2\rho \int f_0(r') \alpha(r') \alpha(\mathbf{r}' - \mathbf{r}) d\mathbf{r}' \right. \\ \left. - \frac{1}{2} \rho^2 a^2(r) - 2\rho^2 \int a(r') \alpha(r') \alpha(\mathbf{r}' - \mathbf{r}) d\mathbf{r}' \right], \quad (18)$$

where

$$f_0(r) = \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \frac{\{\bar{\rho}\beta(u) + \bar{\rho}^2 r(u)\}^2}{1 - \bar{\rho}\beta(u) - \bar{\rho}^2 r(u)} \exp(-iur), \quad (19)$$

or

$$g(r) = \exp(-\phi(r)/kT) \left[1 + \{1 + \rho a(r)\} \bar{f}_0(r) + 2\rho \int \bar{f}_0(r') \alpha(r') \alpha(r' - r) dr' \right. \\ \left. - \{1 + \rho a(r)\}^2 \alpha(r) - \frac{1}{2} \rho^2 a^2(r) \right. \\ \left. - \int \{2\rho \alpha^2(r') + 2\rho^2 \alpha(r') a(r') + 2\rho^2 \alpha^2(r') a(r')\} \alpha(r' - r) dr' \right], \quad (18')$$

where

$$\bar{f}_0(r) = \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \frac{\bar{\rho}\beta(u) + \bar{\rho}^2 r(u)}{1 - \bar{\rho}\beta(u) - \bar{\rho}^2 r(u)} \exp(-iur). \quad (19')$$

It should be noted that the number density ρ , instead of $\bar{\rho}$, is used in Eqs. (18) and (18').

As is well known, the pressure p and the internal energy E can be expressed in terms of $g(r)$ as⁽¹¹⁾

$$\frac{p}{\rho kT} = 1 - \frac{\rho}{6kT} \int r \frac{d\phi(r)}{dr} g(r) dr \quad (20)$$

and

$$\frac{E}{NkT} = \frac{3}{2} + \frac{\rho}{2kT} \int \phi(r) g(r) dr. \quad (21)$$

We have proved in the previous paper⁽¹⁰⁾ that relation (16) is consistent with Eqs. (20) and (21). In our present case we can verify directly that the use of Eq. (18) in Eqs. (20) and (21) gives Eqs. (13) and (14) respectively.

We shall define the function $S(k)$, which is closely related with the intensity of X-rays scattered by the fluid, by

$$S(k) = 1 + \rho \int [g(r) - 1] \exp(ikr) dr. \quad (22)$$

Using Eq. (18) in Eq. (22) we obtain

$$S(k) = 1 + \bar{\rho}\beta(k) + S_0(k) + \frac{1}{(2\pi)^{3/2}} \int du \beta(u - k) S_0(u), \quad (23)$$

where

$$S_0(k) = \frac{\{\bar{\rho}\beta(k) + \bar{\rho}^2 r(k)\}^2}{1 - \bar{\rho}\beta(k) - \bar{\rho}^2 r(k)} - 2\bar{\rho}^3 \beta(k) r(k) - \frac{1}{2} \frac{\bar{\rho}^3}{(2\pi)^{3/2}} \int du \beta^2(u) \beta^2(u - k) \\ + \frac{\bar{\rho}}{(2\pi)^{3/2}} \int du \frac{\{\bar{\rho}\beta(u) + \bar{\rho}^2 r(u)\}^2}{1 - \bar{\rho}\beta(u) - \bar{\rho}^2 r(u)} \{\beta^2(u - k) + 2\beta(k)\beta(u - k)\}.$$

We obtain, in particular,

$$S(0) = 1 + \bar{\rho}\beta(0) + S_0(0) + \frac{1}{(2\pi)^{3/2}} \int du \beta(u) S_0(u). \quad (24)$$

From Eq. (13) we obtain

$$\frac{1}{kT} \left(\frac{\partial p}{\partial \rho} \right)_T = 1 - \bar{\rho}\beta(0) + \frac{1}{(2\pi)^{3/2}} \frac{1}{\bar{\rho}} \int du \left[-\frac{1}{2} \frac{\{\bar{\rho}\beta(u) + 2\bar{\rho}^2 r(u)\}^2}{\{1 - \bar{\rho}\beta(u) - \bar{\rho}^2 r(u)\}^2} - \frac{\bar{\rho}^2 r(u)}{1 - \bar{\rho}\beta(u) - \bar{\rho}^2 r(u)} \right. \\ \left. + \frac{1}{2} \bar{\rho}^2 \beta^2(u) + \bar{\rho}^2 r(u) + 3\bar{\rho}^3 \beta(u) r(u) + 3\bar{\rho}^4 \beta^2(u) r(u) + 3\bar{\rho}^4 r^2(u) \right]. \quad (25)$$

In an exact theory there should be the relation

$$kT\left(\frac{\partial \rho}{\partial p}\right)_T = S(0) \quad (26)$$

or

$$kT\left(\frac{\partial \rho}{\partial p}\right)_T = 1 + \rho \int [g(r) - 1] dr. \quad (26')$$

It can be seen that relation (26) is not satisfied by Eqs. (24) and (25), that is, the netted ring approximation is not consistent with Eq. (26).

§ 4. Discussion

The radial distribution function $g^{n,e}(r)$ based on the netted chain approximation of Rushbrooke and Scoins¹⁾ is

$$g^{n,e}(r) = \exp(-\phi(r)/kT)[1 + f_0(r)], \quad (27)$$

where $f_0(r)$ is defined by Eq. (19). Rushbrooke and Scoins have related a critical point to a singularity of $f_0(r)$ and obtained $p/\rho kT = 1/3$ at a critical point. Since our expression (18) also has the function $f_0(r)$, our theory ought to lead to the same result as above if the conjecture of Rushbrooke and Scoins is well-founded.

It is an open question whether the singularity of $f_0(r)$ is related to a phase change of fluids or not. If, however, we assume that the singularity of $f_0(r)$ is related to a phase change, we shall find an interesting fact that, even in the case of the gas of hard spheres, there will be a phase change. In fact we obtain^{1), 6)} for hard spheres of diameter a

$$\beta(u) = \sqrt{\frac{2}{\pi}} \frac{1}{u^3} [ua \cos ua - \sin ua]$$

and

$$\begin{aligned} \gamma(u) = & \frac{1}{24\pi} \frac{1}{u^6} [-24 - 24(ua)^2 \\ & + \{24 + 12(ua)^2 + 5(ua)^4\} \cos ua \\ & + \{24ua + 4(ua)^3\} \sin ua]. \end{aligned}$$

The singularity of $f_0(r)$ occurs when the equation

$$1 - \bar{\rho}\beta(u) - \bar{\rho}^2\gamma(u) = 0 \quad (28)$$

possesses real roots. As the number density ρ is increased, it can be shown that Eq. (28) begins to possess real roots at a value

$$\rho = 0.86\rho_{\max} \text{ or } v = 1.16v_{\min}$$

where $\rho_{\max} = \sqrt{2}/a^3$ is the maximum density of the gas of hard spheres, and $v = 1/\rho$ and $v_{\min} = 1/\rho_{\max}$. It should be compared with $v/v_{\min} \approx 1.55 \sim 1.60$ obtained by the use of

Monte Carlo method¹²⁾ or detailed molecular dynamics¹³⁾ and also compared with $v/v_{\min} = 1.48$ obtained by the superposition theory¹⁴⁾. It ought to be noted that the simple chain theory does not give such a singularity in the case of hard spheres, because the equation

$$1 - \bar{\rho}\beta(u) = 0$$

possesses no real root for the value of ρ smaller than $\rho_{\max}$.

As has been stated in the preceding section, our netted ring approximation is not consistent with Eq. (26). For quantitative investigation of this point we shall again consider the gas of hard spheres. When a radial distribution function is given, the pressure can be calculated either by Eq. (20) or by Eq. (26'). It is needless to say that both equations lead to the same expression for the pressure if the exact distribution function is used. Our expression (18) gives

$$D_p = 0.4453b^3 \text{ and } D_e = 0.2092b^3,$$

where D_p and D_e are the fourth virial coefficients of the pressure obtained by the use of Eqs. (20) and (26') respectively and $b = 2\pi a^3/3$. These values should be compared with the exact value $D = 0.2869b^3$.¹⁵⁾ They should be also compared with the values based on several theories:

Born-Green non-linear integral equation:^{16), 17)}

$$D_p = 0.2252b^3, \quad D_e = 0.3424b^3$$

netted chain approximation:¹⁾

$$D_p = 0.2500b^3, \quad D_e = 0.2969b^3$$

Rodriguez (1957):¹⁸⁾

$$D_p = D_e = 0.2773b^3.$$

As can be seen above, our theory does not give any better result than earlier theories so far as the fourth virial coefficient in the case of hard spheres is concerned. However it may be not the case for more general

forms of interaction potential. Further our theory will be more suitable than other theories for the investigation of thermodynamic properties of fluids, since the thermodynamic quantities can be given the explicit expressions such as Eqs. (13), (14) and (15). A generalization of our theory to fluid mixtures and a numerical analysis for the case of definite interaction potential will be attempted in later papers.

The author is much indebted to Professor H. Ichimura, Mr. R. Abe and Mr. T. Morita for their fruitful discussions. A part of this work was supported by the Scientific Research Expenditure of the Ministry of Education.

Effect of Transverse Magnetic Field on the Flow due to an Oscillating Flat Plate

By Tsunehiko KAKUTANI

Department of Physics, Faculty of Science, University of Kyoto

(Received August 14, 1958)

Under the well-known assumption in magnetohydrodynamics, the distributions of velocity, magnetic field, and related quantities such as pressure, electric field and current density are obtained for the flow of an incompressible, viscous and electrically conducting fluid due to an infinite oscillating flat plate in the presence of transverse magnetic field.

General solutions are first derived and then some special cases are discussed corresponding to limiting values of parameters such as magnetic pressure number S and magnetic Reynolds number R_m .

It is found that each of the velocity distribution and other related quantities consists of two different oscillations whose decaying factors differ from the corresponding wave numbers, which contrasts to the well-known velocity distribution in classical hydrodynamics.

§ 1. Introduction

In recent years, the subject of magnetohydrodynamics has attracted many authors in view not only of its own interest but also of the applications to the geophysical and astronomical problems.

The general equations of unified velocity and magnetic fields for the flow of an incompressible, viscous and electrically conducting fluid subject to a magnetic field have been derived by Batchelor¹⁾. More recently, Cowling²⁾ published a monograph which contains important reviews and references on this subject so far reported.

In this paper, we discuss the effect of transverse magnetic field on the flow due to an oscillating plate, which is one of the most familiar problems in the classical hydrodynamics in the absence of magnetic field, and an exact solution is obtained for the modified Navier-Stokes and Maxwell's equations under usual assumption in magnetohydrodynamics.

§ 2. Fundamental Equations

The fundamental equations of magnetohydrodynamics are:

(1) Maxwell's equations:

$$\operatorname{div} \mathbf{E} = 4\pi c^2 q / \varepsilon, \quad (2.1)$$

$$\operatorname{div} \mathbf{H} = 0, \quad (2.2)$$

$$\operatorname{curl} \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t}, \quad (2.3)$$

$$\operatorname{curl} \mathbf{H} = 4\pi \mathbf{j} + \frac{\varepsilon}{c^2} \frac{\partial \mathbf{E}}{\partial t}; \quad (2.4)$$

(2) Ohm's law:

$$\mathbf{j} = \sigma(\mathbf{E} + \mu \mathbf{v} \times \mathbf{H}) + q\mathbf{v}; \quad (2.5)$$

(3) The equation of continuity:

$$\operatorname{div} \mathbf{v} = 0; \quad (2.6)$$

(4) The modified Navier-Stokes equation:

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \operatorname{grad}) \mathbf{v} = -\frac{1}{\rho} \operatorname{grad} p + \nu \nabla^2 \mathbf{v} + \frac{\mu}{\rho} \mathbf{j} \times \mathbf{H} + \frac{q}{\rho} \mathbf{E}. \quad (2.7)$$

Here, $\mathbf{E}$ is the electric field, $\mathbf{H}$ the magnetic field, $\mathbf{j}$ the current density, q the excess charge density, ε the dielectric constant, μ the magnetic permeability, σ the electrical conductivity, c the speed of light, $\mathbf{v}$ the velocity of the fluid p the pressure, and ρ and ν are respectively the density and the kinematic coefficient of viscosity of the fluid. All electromagnetic quantities are measured in electromagnetic unit. ε and μ are assumed to be uniform throughout the whole field, and the fluid is assumed to be non-magnetic.

As in most analysis in magnetohydrodynamics, the displacement current in (2.4) may be neglected, since no oscillations of very high frequency occur and the magnitude of the fluid velocity $|\mathbf{v}|$ is much smaller than the speed of light c . In consistence with the above assumption, the convection current in (2.5) and the electric force due to excess charges in (2.7) are also ignored. In the following analysis, Eqs. (2.4), (2.5) and (2.7) should be understood to have been simplified

by the above assumptions.

Eliminating electric field $\mathbf{E}$ between (2.3) and (2.5) with the help of (2.2) and (2.4), we have the magnetic equation as follows:

$$\frac{\partial \mathbf{H}}{\partial t} = \text{curl}(\mathbf{v} \times \mathbf{H}) + \eta \nabla^2 \mathbf{H}, \quad (2.8)$$

where $\eta = 1/(4\pi\mu\sigma)$ which is interpreted as a magnetic diffusivity or a magnetic viscosity. On the other hand, elimination of $\mathbf{j}$ between (2.4) and (2.7) leads to the dynamical equation containing no electromagnetic variables other than $\mathbf{H}$:

$$\begin{aligned} & \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \text{grad}) \mathbf{v} \\ &= -\frac{1}{\rho} \text{grad } p + \nu \nabla^2 \mathbf{v} + \frac{\mu}{4\pi\rho} (\text{curl } \mathbf{H} \times \mathbf{H}). \end{aligned} \quad (2.9)$$

Equations (2.8) and (2.9), together with (2.2) and (2.6), are the fundamental equations of magnetohydrodynamics.

In the present problem, we take the coordinate origin O at an arbitrary point on the oscillating plate, which is assumed to be non-conducting and non-magnetic, and use Cartesian coordinates x , y and z , with the axis Ox in the direction of oscillation and Oy perpendicular to the plate. It is then plausible to assume that

- (1) The flow is parallel to the plate, that is, $\mathbf{v} = v(u, 0, 0)$;
- (2) The magnetic field imposed is uniform and perpendicular to the plate. Thus in the region considered, $\mathbf{H} = \mathbf{H}(H_x, H_y, 0)$;
- (3) All quantities are functions of the space coordinate y and time t only.

The fundamental equations of our problem now become

$$\frac{\partial u}{\partial t} = \nu \frac{\partial^2 u}{\partial y^2} + \frac{\mu}{4\pi\rho} H_y \frac{\partial H_x}{\partial y}, \quad (2.10)$$

$$\frac{\partial}{\partial y} \left(\frac{p}{\rho} + \frac{\mu}{8\pi\rho} H_x^2 \right) = 0, \quad (2.11)$$

$$\frac{\partial H_x}{\partial t} = H_y \frac{\partial u}{\partial y} + \eta \frac{\partial^2 H_x}{\partial y^2}, \quad (2.12)$$

$$\frac{\partial H_y}{\partial t} = \eta \frac{\partial^2 H_y}{\partial y^2}, \quad (2.13)$$

while the equation of continuity (2.6) is automatically satisfied by the above assumptions.

The boundary conditions for the velocity field are exactly the same as those in ordinary hydrodynamics, namely, on the oscillating plate the velocity of the fluid coincides with

that of the plate, and at a great distance from the plate u tends to zero. Thus we have

$$y=0: u = Ue^{i\omega t}; \quad y \rightarrow \infty: u \rightarrow 0, \quad (2.14a)$$

where U and ω denote respectively the velocity amplitude and angular frequency of the oscillating plate.

The boundary conditions for the magnetic field are that both the tangential component of the magnetic field and the normal component of the magnetic induction are continuous at the plate. Since, however, both the fluid and the plate are assumed to be non-magnetic in the present problem, the continuity condition for the magnetic induction may be replaced by that for the magnetic field itself. The total magnetic field at the plate is the vector sum of the imposed and induced fields, the latter resulting from the induced current distribution in the fluid. This distribution depends on the solution and is therefore unknown. The induced field at the plate, however, is secondarily important and may be neglected as compared with the imposed field. On the other hand, since the velocity tends to zero asymptotically at far distance from the plate, no interactions exist there. Hence the magnetic field tends to the imposed field H_0 as $y \rightarrow \infty$. Since the imposed magnetic field H_0 is uniform and perpendicular to the oscillating plate which is non-conducting and non-magnetic, the boundary conditions for the magnetic field may be

$$y=0: H_y = H_0; \quad y \rightarrow \infty: H_y \rightarrow H_0, \quad (2.14b)$$

and

$$y=0: H_x = 0; \quad y \rightarrow \infty: H_x \rightarrow 0. \quad (2.14c)$$

The latter conditions (2.14c) imply that the total flux of current in the direction Oy is taken to be zero, because $\mathbf{j} = (1/4\pi) \text{curl } \mathbf{H}$.

Our problem is to determine the four unknowns u , H_x , H_y and p from Eqs. (2.10)~(2.13) together with the boundary conditions (2.14 a, b, c).

3. Analysis and General Solutions

If the pressure at infinity is p_∞ , it follows immediately from (2.11) that

$$p + \frac{\mu}{8\pi} H_x^2 = p_\infty, \quad (3.1)$$

which shows the balance between the fluid pressure and 'magnetic pressure' in the flow

field, because H_y is uniform throughout the whole flow field as will be shown below. Remembering the boundary conditions for H_y , we can easily solve Eq. (2.13) and obtain

$$H_y \equiv H_0 \quad (3.2)$$

Introducing (3.2) into (2.10) and (2.12) and eliminating H_x between them we have

$$\left[\left(\nu \frac{\partial^2}{\partial y^2} - \frac{\partial}{\partial t} \right) \left(\eta \frac{\partial^2}{\partial y^2} - \frac{\partial}{\partial t} \right) - k \frac{\partial^2}{\partial y^2} \right] u = 0, \quad (3.3)$$

where $k = \mu H_0^2 / (4\pi\rho)$. If we eliminate u instead of H_x we have a similar equation for H_x to (3.3). In the limiting case of $\nu \rightarrow 0$, $\eta \rightarrow 0$, (3.3) and the similar equation for H_x reduce to Alfvén's³⁾ equation for 'magnetohydrodynamic waves'.

Assuming $u \propto e^{\kappa t + \lambda y}$ and inserting it into (3.3), we have

$$(\nu\lambda^2 - \kappa)(\eta\lambda^2 - \kappa) - k\lambda^2 = 0,$$

which gives

$$\lambda = \pm \lambda_1, \pm \lambda_2,$$

where

$$\lambda_{1,2} = \left[\frac{(k + \kappa\nu + \kappa\eta) \pm \{(k + \kappa\nu + \kappa\eta)^2 - 4\nu\eta\kappa^2\}^{1/2}}{2\nu\eta} \right]^{1/2},$$

Re $(\lambda_{1,2}) > 0$,

signs + and - in the square bracket corresponding to λ_1 and λ_2 respectively*. Thus we have the following formal expression for u :

$$u = \sum_{\kappa} e^{\kappa t} [Ae^{\lambda_1 y} + Be^{-\lambda_1 y} + Ce^{\lambda_2 y} + De^{-\lambda_2 y}],$$

where A , B , C and D are constants of integration which depend on the parameter κ , and symbol $\sum$ denotes the summation or integration over all possible values of κ .

It is easily seen that we have to put $A = C = 0$ by virtue of the boundary condition at infinity for u . On the other hand, from the boundary condition on the plate it is required that

$$\kappa = i\omega \quad \text{and} \quad B + D = U. \quad (3.4)$$

Thus we have a formal solution for u as follows:

$$u(y, t) = e^{i\omega t} [Be^{-\lambda_1 y} + De^{-\lambda_2 y}], \quad (3.5)$$

with

$$\lambda_{1,2} = \left[\frac{(k + i\omega(\nu + \eta)) \pm \{(k + i\omega(\nu + \eta))^2 + 4\nu\eta\omega^2\}^{1/2}}{2\nu\eta} \right]^{1/2}. \quad (3.6)$$

Insertion of (3.5) into (2.10) leads to

$$\frac{\partial H_x}{\partial y} = \frac{H_0}{k} e^{i\omega t} [(i\omega - \nu\lambda_1^2)Be^{-\lambda_1 y} + (i\omega - \nu\lambda_2^2)De^{-\lambda_2 y}]. \quad (3.7)$$

Integrating (3.7) with respect to y and remembering that $H_x \rightarrow 0$ when $y \rightarrow \infty$, we have

$$H_x(y, t) = -\frac{H_0}{k} e^{i\omega t} \left[\left(\frac{i\omega}{\lambda_1} - \nu\lambda_1 \right) Be^{-\lambda_1 y} + \left(\frac{i\omega}{\lambda_2} - \nu\lambda_2 \right) De^{-\lambda_2 y} \right]. \quad (3.8)$$

The boundary condition on the plate requires that

$$\left(\frac{i\omega}{\lambda_1} - \nu\lambda_1 \right) B + \left(\frac{i\omega}{\lambda_2} - \nu\lambda_2 \right) D = 0. \quad (3.9)$$

Solving (3.4) and (3.9) for B and D , we have

$$B = -\frac{\lambda_1(\nu\lambda_2^2 - i\omega)}{(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} U, \quad D = \frac{\lambda_2(\nu\lambda_1^2 - i\omega)}{(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} U. \quad (3.10)$$

Insertion of B and D thus determined into (3.5) and (3.8) yields

$$u(y, t) = -\frac{(\nu\lambda_1^2 - i\omega)(\nu\lambda_2^2 - i\omega)}{(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} U e^{i\omega t} \left[\frac{\lambda_1}{\nu\lambda_1^2 - i\omega} e^{-\lambda_1 y} - \frac{\lambda_2}{\nu\lambda_2^2 - i\omega} e^{-\lambda_2 y} \right], \quad (3.11)$$

and

* This convention will also be used hereafter.

$$H_x(y, t) = -\frac{(\nu\lambda_1^2 - i\omega)(\nu\lambda_2^2 - i\omega)}{k(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} H_0 U e^{i\omega t} [e^{-\lambda_1 y} - e^{-\lambda_2 y}] \quad (3.12)$$

Putting (3.12) into (2.4), we have

$$\left. \begin{aligned} j_x &= 0, \quad j_y = 0, \\ j_z(y, t) &= -\frac{(\nu\lambda_1^2 - i\omega)(\nu\lambda_2^2 - i\omega)}{4\pi k(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} H_0 U e^{i\omega t} [\lambda_1 e^{-\lambda_1 y} - \lambda_2 e^{-\lambda_2 y}]. \end{aligned} \right\} \quad (3.13)$$

Also, putting (3.11), (3.12) and (3.13) into (2.5) we have

$$\left. \begin{aligned} E_x &= 0, \quad E_y = 0, \\ E_z(y, t) &= -\frac{i\omega(\nu\lambda_1^2 - i\omega)(\nu\lambda_2^2 - i\omega)}{k(\lambda_1 - \lambda_2)(\lambda_1\lambda_2\nu + i\omega)} \mu H_0 U e^{i\omega t} \left[\frac{1}{\lambda_1} e^{-\lambda_1 y} - \frac{1}{\lambda_2} e^{-\lambda_2 y} \right]. \end{aligned} \right\} \quad (3.14)$$

The above (3.11)~(3.14), together with (3.1) and (3.2), give the general solutions of the present problem. It will be seen that all quantities consist of two different oscillations whose complex decaying factors are $\lambda_{1,2}$, $\text{Re}(\lambda_{1,2})$ and $\text{Im}(\lambda_{1,2})$ representing the decaying factors and the wave numbers respectively. The above result should be compared with that of the well-known classical hydrodynamics: $u = U e^{i\omega t - \sqrt{i\omega\nu} y}$. Since $H_y = H_0$, the fundamental equations (2.10), (2.11), (2.12) and (2.13) are all linear. Hence we can make up more general solutions by superposing several oscillations of different frequencies and amplitudes so long as the angular frequencies ω and amplitudes U are not so extremely large as to make displacement current important.

The skin friction τ can be easily obtained from the formula

$$\tau = \left(\rho \nu \frac{\partial u}{\partial y} \right)_{y=0},$$

which yields

$$\tau = \text{Re} \left[-\rho \nu U e^{i\omega t} \left\{ \frac{i\omega(\lambda_1 + \lambda_2)}{\lambda_1\lambda_2\nu + i\omega} \right\} \right].$$

On the other hand, the drag on the plate due to the direct magnetic effect is zero, because

$$\int_0^\infty \frac{\mu}{4\pi\rho} H_0 \frac{\partial H_x}{\partial y} dy = 0.$$

In order to clarify the magnetic effect, we shall consider, in the next section, the behaviours of the solutions in some special cases corresponding to the limiting values of parameters such as magnetic pressure number S and magnetic Reynolds number R_m .

§ 4. Behaviours of the Solutions in Some Special Cases

For proceeding further, it is convenient to define some non-dimensional parameters such as

$$\left. \begin{aligned} \text{Reynolds number: } R &= \frac{U^2}{\nu\omega}, \\ \text{Magnetic Reynolds number: } R_m &= \frac{U^2}{\eta\omega}, \\ \text{Magnetic pressure number: } S &= \frac{\mu H_0^2}{4\pi\rho U^2}, \end{aligned} \right\} \quad (4.1)$$

and to introduce non-dimensional quantities with asterisk as follows:

$$\left. \begin{aligned}
 u &= Uu^*, & p &= \frac{1}{2}\rho U^2 p^*, \\
 y &= \frac{U}{\omega} y^*, & H &= H_0 H^*, \\
 t &= \frac{1}{\omega} t^*, & E &= \mu H_0 U E^*, \\
 \lambda_{1,2} &= \frac{\omega}{U} \lambda_{1,2}^*, & j &= \sigma \mu H_0 U j^*.
 \end{aligned} \right\} \quad (4.2)$$

It is to be noted here that the Hartmann number M frequently used in the analysis of problems in magnetohydrodynamics is equal to $\sqrt{SRR_m}$ in our notation.

Then the solutions expressed in non-dimensional forms are:

$$u^* = -\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} e^{it^*} \left[\frac{\lambda_1^*}{\lambda_1^{*2} - iR} e^{-\lambda_1^* y^*} - \frac{\lambda_2^*}{\lambda_2^{*2} - iR} e^{-\lambda_2^* y^*} \right], \quad (4.3)$$

$$H_z^* = -\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{SR(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} e^{it^*} [e^{-\lambda_1^* y^*} - e^{-\lambda_2^* y^*}], \quad (4.4)$$

$$E_z^* = -\frac{i(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{SR(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} e^{it^*} \left[\frac{1}{\lambda_1^*} e^{-\lambda_1^* y^*} - \frac{1}{\lambda_2^*} e^{-\lambda_2^* y^*} \right], \quad (4.5)$$

$$j_z^* = -\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{SRR_m(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} e^{it^*} [\lambda_1^* e^{-\lambda_1^* y^*} - \lambda_2^* e^{-\lambda_2^* y^*}], \quad (4.6)$$

$$p^* + SH_z^{*2} = p_\infty^*, \quad (4.7)$$

with

$$\lambda_{1,2}^* = \left[\frac{SRR_m + i(R + R_m) \pm \{(SRR_m + i(R + R_m))^2 + 4RR_m\}^{1/2}}{2} \right]^{1/2}. \quad (4.8)$$

There are the three characteristic parameters S , R and R_m in this problem. Since, however, R and R_m are contained symmetrically in $\lambda_{1,2}^*$, we have only to discuss the cases of the limiting values of S and R_m instead of those of S , R and R_m .

In the following discussions, only the first dominant terms are retained in each case.

(1) $S \ll 1$.

In this case, if $R > R_m$

$$\lambda_1^* \sim \sqrt{iR} \left(1 - \frac{SRR_m}{2(R - R_m)} i \right), \quad \lambda_2^* \sim \sqrt{iR_m} \left(1 + \frac{SRR_m}{2(R - R_m)} i \right). \quad (4.9)$$

Hence, $\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} \sim -\frac{SR^2 R_m}{\sqrt{iR}(R - R_m)}$, so that

$$\left. \begin{aligned}
 u^* &\sim \frac{SR^2 R_m}{\sqrt{iR}(R - R_m)} e^{it^*} \left[\frac{\sqrt{iR}(R - R_m)}{SR^2 R_m} e^{-\sqrt{iR} y^*} - \frac{i\sqrt{iR_m}}{R - R_m} e^{-\sqrt{iR_m} y^*} \right], \\
 H_z^* &\sim \frac{RR_m}{\sqrt{iR}(R - R_m)} e^{it^*} [e^{-\sqrt{iR} y^*} - e^{-\sqrt{iR_m} y^*}], \\
 E_z^* &\sim \frac{iRR_m}{\sqrt{iR}(R - R_m)} e^{it^*} \left[\frac{1}{\sqrt{iR}} e^{-\sqrt{iR} y^*} - \frac{1}{\sqrt{iR_m}} e^{-\sqrt{iR_m} y^*} \right], \\
 j_z^* &\sim \frac{R}{\sqrt{iR}(R - R_m)} e^{it^*} [\sqrt{iR} e^{-\sqrt{iR} y^*} - \sqrt{iR_m} e^{-\sqrt{iR_m} y^*}].
 \end{aligned} \right\} \quad (4.10)$$

In the limit of $S \rightarrow 0$, u^* tends to the solution of the classical hydrodynamics as expected. If $R < R_m$, λ_1^* takes the place of λ_2^* in (4.9) and *vice versa*. Since, however, λ_1^* and λ_2^* are contained symmetrically in u^* , H_z^* , E_z^* and j_z^* , the final expressions (4.10) remain unaltered.

(2) $S \gg 1$.

In this case, $\lambda_1^* \sim \sqrt{SRR_m} \left(1 + \frac{R+R_m}{2SRR_m} i\right)$ and $\lambda_2^* \sim \frac{i}{\sqrt{S}} \left(1 - \frac{R+R_m}{2SRR_m} i\right)$. Hence, $\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} \sim -\frac{R\sqrt{SR_m}}{\sqrt{R} + \sqrt{R_m}}$, and therefore

$$\left. \begin{aligned} u^* &\sim \frac{R\sqrt{SR_m}}{\sqrt{R} + \sqrt{R_m}} e^{it^*} \left[\frac{1}{\sqrt{SRR_m}} e^{-\sqrt{SR_m} y^*} + \frac{1}{R\sqrt{S}} e^{-i/\sqrt{S} \cdot y^*} \right], \\ H_x^* &\sim \frac{\sqrt{R_m}}{\sqrt{S}(\sqrt{R} + \sqrt{R_m})} e^{it^*} [e^{-\sqrt{SR_m} y^*} - e^{-i/\sqrt{S} \cdot y^*}], \\ E_z^* &\sim \frac{i\sqrt{R_m}}{\sqrt{S}(\sqrt{R} + \sqrt{R_m})} e^{it^*} \left[\frac{1}{\sqrt{SRR_m}} e^{-\sqrt{SR_m} y^*} + i\sqrt{S} e^{-i/\sqrt{S} \cdot y^*} \right], \\ j_z^* &\sim \frac{1}{\sqrt{SR_m}(\sqrt{R} + \sqrt{R_m})} e^{it^*} \left[\sqrt{SR_m} e^{-\sqrt{SR_m} y^*} - \frac{i}{\sqrt{S}} e^{-i/\sqrt{S} \cdot y^*} \right]. \end{aligned} \right\} \quad (4.11)$$

Thus the first terms of each quantity decay rapidly with increasing y and are vanishingly small except for the vicinity of the plate, and the second terms become dominant which represent the oscillations whose phase velocity is the same as that of the magnetohydrodynamic waves of Alfvén. Because the decaying factors of the second terms of each quantity are of higher order in $(1/S)$ than the wave number terms, the second terms decay very slowly.

(3) $R_m \ll 1$.

Since $\lambda_1^* \sim \sqrt{iR}(1 - \frac{1}{2}SR_m i)$ and $\lambda_2^* \sim \sqrt{iR_m}(1 + \frac{1}{2}SR_m i)$, $\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} \sim -\frac{SR_m}{\sqrt{iR}}$. Hence, the general character of the solutions is similar to that in the case (1).

(4) $R_m \gg 1$.

In this case $\lambda_1^* \sim \sqrt{R_m(SR+i)} \left(1 + \frac{SR^2}{2R_m(SR+i)^2} i\right)$ and $\lambda_2^* \sim \sqrt{\frac{R}{SR+i}} i \left(1 - \frac{SR^2}{2R_m(SR+i)^2} i\right)$. Hence, $\frac{(\lambda_1^{*2} - iR)(\lambda_2^{*2} - iR)}{(\lambda_1^* - \lambda_2^*)(\lambda_1^* \lambda_2^* + iR)} \sim -\frac{SR^2}{\sqrt{R(SR+i)}}$, so that

$$\left. \begin{aligned} u^* &\sim \frac{SR^2}{\sqrt{R(SR+i)}} e^{it^*} \left[\frac{1}{\sqrt{R_m(SR+i)}} e^{-\sqrt{R_m(SR+i)} y^*} + \frac{\sqrt{R(SR+i)}}{SR^2} e^{-\sqrt{R/(SR+i)} y^*} \right], \\ H_x^* &\sim \frac{R}{\sqrt{R(SR+i)}} e^{it^*} [e^{-\sqrt{R_m(SR+i)} y^*} - e^{-\sqrt{R/(SR+i)} y^*}], \\ E_z^* &\sim \frac{iR}{\sqrt{R(SR+i)}} e^{it^*} \left[\frac{1}{\sqrt{R_m(SR+i)}} e^{-\sqrt{R_m(SR+i)} y^*} + \sqrt{\frac{SR+i}{R}} i e^{-\sqrt{R/(SR+i)} y^*} \right], \\ j_z^* &\sim \frac{R}{R_m \sqrt{R(SR+i)}} e^{it^*} \left[\sqrt{R_m(SR+i)} e^{-\sqrt{R_m(SR+i)} y^*} - \sqrt{\frac{R}{SR+i}} i e^{-\sqrt{R/(SR+i)} y^*} \right]. \end{aligned} \right\} \quad (4.12)$$

Hence, the general character is similar to that in the case (2) except that the decaying factors of the second terms in this case are of the same order as the wave number terms. Therefore, even the second terms which are of course dominant over the first terms decrease normally as the distance from the plate increases.

Acknowledgement

The writer wishes to express his cordial thanks to Professor S. Tomotika for his continual guidance and encouragement throughout the present study, and especially

for his kind inspection of the manuscript. The writer's thanks are also due to Professor K. Tamada, Dr. H. Hasimoto, Messrs. H. Yosinobu and K. Gotoh for their invaluable advices and helpful discussions at every stage.

Some Nonlinear Effect in Compressible Flow

By Haruo MORIGUCHI

*Department of Physics, Faculty of Liberal Arts,
Shizuoka University, Shizuoka, Japan*

(Received August 30, 1958)

The two-dimensional potential flow of a compressible fluid past a family of cylindrical obstacles with two parameters which includes elliptic cylinder and Kaplan bump is investigated by use of Imai's method.

An very interesting example has been found such that the surface velocity distribution changes its character with increasing Mach number, namely, it has two maxima for $M=0$, which tend to coalesce into one as the Mach number increases. Such an effect, however, is very small within the approximation used.

§ 1. The Shape of Cylinder and Incompressible Flow

In this paper we shall consider a family of symmetrical profiles in the complex z -plane which are obtained by means of the transformation

a: Profiles for $\alpha=0$ and Kaplan bump with thickness ratio $2/9$.

b: Profiles with the same thickness ratio 0.9312 as Cherry's profile.

Fig. 1. Examples of profiles.

(Because of symmetry, only the parts in the first quadrant are shown).

$$z = \zeta + \frac{a^2}{\zeta} - \frac{c^4}{3\zeta^3}$$

from the unit circle $\zeta = e^{i\theta}$ in the complex ζ -plane.

For $c=0$ our obstacle reduces to an elliptic cylinder, for $c^4=a^2-1$ a Kaplan bump with thickness ratio $t=-4c^4/(6+2c^2)$ is obtained and for $c=1$ a profile with four cusps and similar to an asteroid. An obstacle which is similar to Cherry's profile¹⁾ is also included in this family. Some examples are shown in Fig. 1.

Taking the undisturbed flow velocity as unit, the incompressible flow past our profile

Fig. 2. Examples of incompressible flows for profiles with $\alpha=0$.

is given by the complex velocity potential

$$F_0 = \zeta + \frac{1}{\zeta} \quad (1.1)$$

and the surface velocity q_0 is given by

$$q_0^2 = \left| \left(\frac{dF_0}{dz} \right)_p \right|^2 = 2 \frac{1 - \cos 2\theta}{1 - 2a^2(1 + c^4) \cos 2\theta + 2c^4 \cos 4\theta + a^4 + c^8} \quad (1.2)$$

where the suffix p denotes the value on the profile. In this flow the velocity distribution has two maxima when

$$c^4 > 7 + a^2 - 4\sqrt{3 + a^2}, \quad (1.3)$$

and one maximum when

$$c^4 \leq 7 + a^2 - 4\sqrt{3 + a^2}, \quad (1.4)$$

here as well as in what follows we suppose $0 \leq a < 1$. Fig. 2 shows some examples.

§ 2. The Compressibility Effect

We shall calculate the compressibility effect for the flow given in the preceding section up to the order of M^2 by use of Imai's method²⁾, where M is the free stream Mach number.

When the velocity potential on the surface of the obstacles expanded as

$$\varphi(\theta) = \varphi_0(\theta) + M^2 \varphi_1(\theta) + O(M^4) \quad (2.1)$$

$$\varphi_0(\theta) = 2 \cos \theta, \quad (2.2)$$

then, according to Imai's formulas, we have

$$\varphi_1(\theta) = P_1(\theta) - Q_1^*(\theta) \quad (2.3)$$

$$P_1(\theta) + iQ_1(\theta) = \frac{1}{4} \frac{d\varphi_0}{d\theta} \frac{d\theta}{ds} e^{-i\omega} \int_0^\theta \left(\frac{d\varphi_0}{d\theta} \right)^2 \frac{d\theta}{ds} e^{i\omega} d\theta - \frac{1}{4} (e^{i\theta} + e^{-i\theta}) \quad (2.4)$$

$$\frac{ds}{d\theta} e^{-i\omega} = \frac{dz_p}{d\theta}, \quad (2.5)$$

where s denotes the length along the surface of the obstacle and $Q_1^*(\theta)$ is the conjugate Fourier series associated with $Q_1(\theta)$. In the case when we can write

$$P_1(\theta) + iQ_1(\theta) = f(e^{i\theta}), \quad (2.6)$$

where $f(u)$ is an analytic function of u , the right-hand side of (2.3) can be expressed as

$$P_1(\theta) - Q_1^*(\theta) = 2Re \left[\frac{1}{2\pi i} \oint \frac{f(u)}{u - e^{i\theta}} du \right], \quad (2.7)$$

where the pass of integration is the unit circle with centre at the origin and with a semi-circular indentation around $u = e^{i\theta}$.

According to § 1,

$$z_p = e^{i\theta} + a^2 e^{-i\theta} - \frac{c^4}{3} e^{-3i\theta}, \quad (2.8)$$

and substituting this expression into (2.4) we have

$$P_1(\theta) + iQ_1(\theta) = \frac{1}{4} \frac{e^{4i\theta} - e^{2i\theta}}{e^{4i\theta} - a^2 e^{2i\theta} + c^4} \left[e^{-i\theta} + C_1 + \frac{1}{\sqrt{a^4 - 4c^4}} \left\{ s_1 \log \frac{1 - u_1 e^{i\theta}}{1 + u_1 e^{i\theta}} - s_2 \log \frac{1 - u_2 e^{i\theta}}{1 + u_2 e^{i\theta}} \right\} \right] - \frac{1}{4} (e^{i\theta} + e^{-i\theta}), \quad (2.9)$$

where

$$s_1 = \frac{1 - c^4}{2u_1} - \frac{2 - a^2}{2} u_1 \quad (2.10)$$

$$s_2 = \frac{1 - c^4}{2u_2} - \frac{2 - a^2}{2} u_2 \quad (2.11)$$

$$u_1^2 = \frac{a^2 + \sqrt{a^4 - 4c^4}}{2} \quad (2.12)$$

$$u_1^2 = \frac{a^2 - \sqrt{a^4 - 4c^4}}{2} \quad (2.13)$$

and C_1 is a constant.

The integral in (2.7) can be calculated as the sum of the residues at six poles included in the contour, and the result is

$$2\varphi_1(\theta) = \operatorname{Re} \left[\frac{1}{e^{4i\theta} - a^2 e^{2i\theta} + c^4} \{ (e^{4i\theta} - e^{2i\theta}) F(\theta) + P e^{i\theta} + Q e^{3i\theta} \} - e^{i\theta} \right], \quad (2.14)$$

where

$$F(\theta) = \left(\frac{1-c^4}{4c^2} - \frac{2-a^2}{4} \right) \frac{1}{\sqrt{a^2-2c^2}} \log \frac{1-\sqrt{a^2-2c^2}e^{i\theta}-c^2e^{2i\theta}}{1+\sqrt{a^2-2c^2}e^{i\theta}-c^2e^{2i\theta}} \\ - \left(\frac{1-c^4}{4c^2} + \frac{2-a^2}{4} \right) \frac{1}{\sqrt{a^2+2c^2}} \log \frac{1-\sqrt{a^2+2c^2}e^{i\theta}+c^2e^{2i\theta}}{1+\sqrt{a^2+2c^2}e^{i\theta}+c^2e^{2i\theta}} \quad (2.15)$$

$$P = \frac{1}{a^4-4c^4} \left\{ p_1 \log \frac{1-c^2}{1+c^2} + p_2 \log \frac{1-a^2+c^4}{1+a^2+c^4} + p_3 \sqrt{a^4-4c^4} \log \frac{1-c^4-\sqrt{a^4-4c^4}}{1-c^4+\sqrt{a^4-4c^4}} \right\} \quad (2.16)$$

$$Q = \frac{1}{a^4-4c^4} \left\{ q_1 \log \frac{1-c^2}{1+c^2} + q_2 \log \frac{1-a^2+c^4}{1+a^2+c^4} + q_3 \sqrt{a^4-4c^4} \log \frac{1-c^4-\sqrt{a^4-4c^4}}{1-c^4+\sqrt{a^4-4c^4}} \right\} \quad (2.17)$$

$$p_1 = \frac{c^2}{2} (2-3a^2+a^4+2c^4-a^2c^4) \quad (2.18)$$

$$p_2 = \frac{1}{4} (-a^2+6c^4-3a^2c^4+a^4c^4-2c^8) \quad (2.19)$$

$$p_3 = \frac{1}{4} (1-3c^4+a^2c^4) \quad (2.20)$$

$$q_1 = \frac{1}{2c^2} (-a^2+a^4+2c^4-3a^2c^4+2c^8) \quad (2.21)$$

$$q_2 = \frac{1}{4} (2-3a^2+3a^4-a^6-6c^4+3a^2c^4) \quad (2.22)$$

$$q_3 = \frac{1}{4} (-3+3a^2-a^4+c^4) \quad (2.23)$$

In these expressions we should write

$$\sqrt{a^4-4c^4} \log \frac{1-c^4-\sqrt{a^4-4c^4}}{1-c^4+\sqrt{a^4-4c^4}} = 2\sqrt{4c^4-a^4} \tan^{-1} \frac{\sqrt{4c^4-a^4}}{1-c^4} \quad (2.24)$$

when

$$4c^4 > a^4.$$

Simple special cases of (2.14) are given as follows:

i) Elliptic cylinder $c \rightarrow 0$:

$$2\varphi_1(\theta) = \operatorname{Re} \left[\frac{1}{e^{2i\theta} - a^2} \left\{ (e^{2i\theta} - 1) \left(\frac{1-2a^2+a^4}{2a^3} \right) \log \frac{1-ae^{i\theta}}{1+ae^{i\theta}} + \frac{e^{3i\theta}}{a^2} + \left(\frac{(1-a^2)^3}{2a^4} \log \frac{1-a^2}{1+a^2} - 1 \right) e^{i\theta} \right\} - e^{i\theta} \right] \quad (2.25)$$

ii) Circular cylinder $a=c \rightarrow 0$:

$$2\varphi_1(\theta) = Re \left[\frac{4}{3} e^{i\theta} - \frac{1}{3} e^{3i\theta} \right] \quad (2.26)$$

iii) Kaplan bump $c^4 = a^2 - 1$:

$$2\varphi_1(\theta) = Re \left[\frac{e^{2i\theta}}{e^{2i\theta} - c^4} \frac{1 - c^4}{2c^2} \log \frac{1 + c^2 e^{i\theta}}{1 - c^2 e^{i\theta}} - e^{i\theta} \right]. \quad (2.27)$$

The surface velocity distribution is given by differentiation of (2.12) and the final result is

$$q_1 = \frac{d\varphi_1(\theta)}{ds} \frac{d\theta}{ds} \quad (2.28)$$

where

$$\frac{d\varphi_1}{d\theta} = \frac{1}{K_2(\theta)} \{ C_R(\theta) Re F(\theta) + C_I(\theta) Im F(\theta) + G(\theta) \} + \frac{H(\theta)}{K(\theta)} + \sin \theta \quad (2.29)$$

$$C_R(\theta) = \alpha_2 \sin 2\theta + \alpha_4 \sin 4\theta + \alpha_6 \sin 6\theta \quad (2.30)$$

$$C_I(\theta) = \beta_0 + \beta_2 \cos 2\theta + \beta_4 \cos 4\theta + \beta_6 \cos 6\theta \quad (2.31)$$

$$G(\theta) = \gamma_1 \sin \theta + \gamma_3 \sin 3\theta + \gamma_5 \sin 5\theta + \gamma_7 \sin 7\theta \quad (2.32)$$

$$r_n = r_{n1} P + r_{n2} Q \quad (n=1, 3, 5, 7) \quad (2.33)$$

$$H(\theta) = \delta_1 \sin \theta + \delta_3 \sin 3\theta \quad (2.34)$$

$$\alpha_2 = 2 - 2a^2 - 2a^4 + 2a^6 + c^4(-4 - 2a^2 + 6a^4) + c^8(-4 + 8a^2) + 2c^{12} \quad (2.35)$$

$$\alpha_4 = c^4(4 + 8a^2 - 12a^4) + 2c^8a^2 - 4c^{12} \quad (2.36)$$

$$\alpha_6 = -2c^4 - 2c^8 \quad (2.37)$$

$$\beta_0 = 4a^2 - 4a^4 + c^4(-2a^2 - 2a^4) + c^8(-8 - 4a^2) \quad (2.38)$$

$$\beta_2 = -2 + 2a^2 - 2a^4 + 2a^6 + c^4(-4 + 14a^2 + 10a^4) + c^8(4 + 8a^2 + 2c^{12}) \quad (2.39)$$

$$\beta_4 = c^4(-4 - 12a^4) + c^8(2a^2 - 4c^{12}) \quad (2.40)$$

$$\beta_6 = 2c^4 - 2c^8 \quad (2.41)$$

$$r_{11} = 6a^2 + 3a^4 + a^6 + c^4(6 - 6a^4) - 2c^8a^2 - c^{12} \quad (2.42)$$

$$r_{31} = -3 - 2a^4 + c^4(2 - 6a^2) + 2c^8 \quad (2.43)$$

$$r_{51} = a^2 - 2a^2c^4 + 3c^8 \quad (2.44)$$

$$r_{71} = c^4 \quad (2.45)$$

$$r_{12} = -1 - 2a^2 + 2a^4 + a^6 + c^4(4a^2 + 3a^4) + c^8(6 + 6a^2) \quad (2.46)$$

$$r_{32} = -a^2 + a^4 + c^4(2 - 6a^2 - 10a^4) \quad (2.47)$$

$$r_{52} = c^4(3 - 2a^2) - c^8a^2 \quad (2.48)$$

$$r_{72} = c^8 \quad (2.49)$$

$$\delta_1 = -5 + 2a^2 + c^4 \quad (2.50)$$

$$\delta_3 = 1 - c^4 \quad (2.51)$$

$$ReF(\theta) = -\mu \frac{1}{2} \log \frac{1+(a^2+2c^2)+c^4+2c^2 \cos 2\theta - 2\sqrt{a^2+2c^2}(1+c^2) \cos \theta}{1+(a^2+2c^2)+c^4+2c^2 \cos 2\theta + 2\sqrt{a^2+2c^2}(1+c^2) \cos \theta}$$

$$+ \nu \begin{cases} \frac{1}{\sqrt{a^2-2c^2}} \frac{1}{2} \log \frac{1+(a^2-2c^2)+c^4-2c^2 \cos 2\theta - 2\sqrt{a^2-2c^2}(1-c^2) \cos \theta}{1+(a^2-2c^2)+c^4-2c^2 \cos 2\theta + 2\sqrt{a^2-2c^2}(1-c^2) \cos \theta} & (a^2 > 2c^2) \\ \frac{-1}{\sqrt{2c^2-a^2}} \tan^{-1} \frac{2\sqrt{2c^2-a^2}(1-c^2) \cos \theta}{1-(2c^2-a^2)+c^4-2c^2 \cos 2\theta} & (a^2 < 2c^2) \end{cases} \quad (2.52)$$

$$ImF(\theta) = \mu \tan^{-1} \frac{2\sqrt{a^2+2c^2}(1-c^2) \sin \theta}{1+c^4-(a^2+2c^2)+2c^2 \cos 2\theta}$$

$$- \nu \begin{cases} \frac{1}{\sqrt{a^2-2c^2}} \tan^{-1} \frac{2\sqrt{a^2-2c^2}(1+c^2) \sin \theta}{1+c^4+(2c^2-a^2)-2c^2 \cos 2\theta} & (a^2 > 2c^2) \\ \frac{1}{\sqrt{2c^2-a^2}} \frac{1}{2} \log \frac{1+(2c^2-a^2)+c^4-2c^2 \cos 2\theta + 2\sqrt{2c^2-a^2}(1+c^2) \sin \theta}{1+(2c^2-a^2)+c^4-2c^2 \cos 2\theta - 2\sqrt{2c^2-a^2}(1+c^2) \sin \theta} & (a^2 < 2c^2) \end{cases} \quad (2.53)$$

$$\mu = \left(\frac{1-c^4}{4c^2} + \frac{2-a^2}{4} \right) \frac{1}{\sqrt{a^2+2c^2}} \quad (2.54)$$

$$\nu = \frac{1-c^4}{4c^2} - \frac{2-a^2}{4} \quad (2.55)$$

$$K(\theta) = 1+a^4+c^8-2a^2(1+c^4) \cos 2\theta + 2c^4 \cos 4\theta \quad (2.56)$$

$$\frac{d\theta}{ds} = -\frac{1}{\sqrt{K(\theta)}} \quad (2.57)$$

§ 3. The Variation of Curvature of the Velocity Distribution Curve

A few years ago, Takami³⁾ calculated the velocity distribution, both for incompressible and purely subsonic flow, over the surface of a special obstacle for which Cherry¹⁾ had shown the existence of continuous mixed flow, and showed that the velocity distribution curve has two maxima, in contrast to the fact that the velocity distribution in the transonic case given by Cherry has only one maximum. Thus it seems to be of some interest to study the manner in which the character of the velocity distribution curve is affected by the free stream Mach number. Our family of profiles seems to be particularly suited for this purpose, since it covers both cases of velocity distribution, one-peak as well as two-peak distribution, for the incompressible flow.

For a qualitative discussion it would be sufficient to study the sign of $d^2q/d\theta^2$. Further, because of symmetry only the value at $\theta = \pi/2$ is necessary. When $d^2q/d\theta^2$ is positive, the flow has two maximum velocities on the surface, and when it is negative, the flow has only one maximum.

To see the possibility of transition between these types of flow we have calculated $d^2q_1/d\theta^2$

in the case of

$$c^4 = 7 + a^2 - 4\sqrt{3+a^2} \quad (3.1)$$

for which the incompressible flow velocity distribution has one flat maximum with zero curvature. The result is shown in Fig. 3, which indicates that the sign is always negative, that is, q_1 has one maximum with finite curvature. In Fig. 4, q_1 is shown for the

Fig. 3. $\left(\frac{d^2q_1}{d\theta^2} \right)_{\theta=\pi/2}$ for $c^4 = 7 + a^2 - 4\sqrt{3+a^2}$.

Fig. 4. The first approximation for the profile with $a=0$, $c^4 = 7 - 4\sqrt{3}$.

simplest case $a=0$, $c^4=7-4\sqrt{3}$. For sufficiently small values of M the M^2 -expansion series is convergent, and the curvature of the velocity distribution curve should have the same sign as $d^2q_1/d\theta^2$ provided that the velocity distribution curve for the incompressible flow has zero curvature.

Now let us consider the case where the value of c^4 exceeds $7+a^2-4\sqrt{3+a^2}$ a little. Then the curvature of q_0 remains unchanged and negative, but the curvature of q_1 becomes positive, that is, q_0 has two maxima and q_1 has only one. Therefore, when the free stream Mach number increases, the velocity distribution has a tendency to assume one-peak distribution instead of two-peak distribution. If c^4 is sufficiently close to $7+a^2-4\sqrt{3+a^2}$ this transition will take place really.

Fig. 5. $\left(\frac{d^2q_0}{d\theta^2}\right)_{\theta=\pi/2}$ and $\left(\frac{d^2q_1}{d\theta^2}\right)_{\theta=3\pi/2}$ for $a=0$.

The next problem is to study whether the transition is observable. For this purpose we need some numerical work. For $a^2=0$ $d^2q_0/d\theta^2$ and $d^2q_1/d\theta^2$ are shown in Fig. 5, which shows that the transition can take place in a very narrow range of c . For such values of c the curvature of q_0 is very small, so that we cannot expect an observable effect. For example, let us consider the incompressible flow for $c=0.729$. In this case the difference between the maximum velocity and minimum velocity at $\theta=\pi/2$ is only about 1/300 percent of the minimum velocity. Outside of the narrow range in the neighborhood of $c^2=2-\sqrt{3}=0.268$ the curvatures of q_0 and q_1 have the same sign, so that the transition cannot take place.

Similar circumstances occur also for other values of a . Therefore such an effect should be regarded as merely mathematical, at least within the first approximation.

§ 4. Comparison with the Case of Cherry's Profile

In this section we shall study the cases in which our profiles have the same thickness ratio 0.9312 as Cherry's profile for which flow of mixed type with Mach number 0.5098 take place. For our family of profiles with thickness ratio 0.9312, the boundary case between one-peak and two-peak distribution in incompressible flow is that corresponding to $a^2=0.0348$, $c^4=0.0665$. As is seen in Fig. 1 Cherry's profile is very similar to the profile for which we have shown the possibility of the transition from two-peak to one-peak velocity distribution. But Takami's result reproduced in Fig. 6 as well as some of our

Fig. 6. Incompressible flows for Cherry's profile³⁾ and our profiles with the same thickness ratio.

family shows that the difference between the maximum and the minimum velocity is quite large. For our family of the same thickness ratio such a sharp two-peak distribution can appear for $a^2=0.0340$ and $c^4=0.133$. Since for $a^2=0.0340$ the value of c^4 corresponding to the boundary case is about 0.0666, the value 0.133 of c^4 is too large to expect the transition phenomenon. We may say that even if the higher order approximations are taken in account, we could not expect the transition. Therefore in spite of the fact that mathematically the transition phenomenon is not ruled out, Takami's conjecture that the

character of the surface velocity distribution for Cherry's profile will be unchanged up to the critical Mach number will probably remain unaffected.

Acknowledgement

In conclusion the writer wishes to express his sincere thanks to Professor I. Imai for his guidance throughout this work and to Mr.

H. Takami for private communication of his numerical data. He is also indebted to the Ministry of Education for a grant.

The Forces experienced by a Lattice of Equal Flat Plates in a Uniform Flow at Small Reynolds Numbers

By Shinji KUWABARA

Department of Physics, Faculty of Science, University of Tokyo

(Received September 1, 1958)

Two-dimensional incompressible viscous flow past a lattice of equal parallel and equidistant flat plates without stagger placed parallel to a uniform flow is studied on the basis of Stokes' approximation by use of the Fourier transformation method. Asymptotic solutions are explicitly obtained for two cases $h \rightarrow \infty$ and $h \rightarrow 0$, where h is the distance between the neighbouring two flat plates.

§ 1. Introduction

Tamada and Fujikawa studied the viscous flow past a lattice of equal parallel circular cylinders on the basis of Oseen's approximation¹⁾ and Miyagi also attacked the same problem on the basis of Stokes' approximation²⁾. Recently, Hasimoto discussed the flow past a thin screen having a series of parallel equal and equidistant slits³⁾. In this paper, we shall study the flow past a lattice of parallel equal and equidistant flat plates without stagger placed parallel equal and equidistant flat plates without stagger placed parallel to a uniform flow. It should be added that Tamada has quite recently discussed the same problem in the general case of arbitrary angle of attack and stagger⁴⁾.

Our studies are based on Stokes' equations of motion and make use of the method of Fourier-transformation which has been successfully applied by Hasimoto to the Rayleigh problem for a plate of finite breadth⁵⁾.

In §§ 3 and 4, we investigate the asymptotic

solutions of the integral equation when $h \rightarrow \infty$ and $h \rightarrow 0$, where h is the distance between the neighbouring two flat plates.

§ 2. Deduction of the Integral Equation for the Vorticity Distribution on the Flat Plate

Stokes' approximate equations of motion and the equation of continuity for the two-dimensional steady flow of an incompressible viscous fluid are

$$\frac{\partial p}{\partial x} = \mu \Delta u, \quad (2.1)$$

$$\frac{\partial p}{\partial y} = \mu \Delta v, \quad (2.2)$$

and

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0, \quad (2.3)$$

where $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2$, (x, y) are the cartesian co-ordinates, (u, v) are the velocity components, p is the pressure and μ is the coefficient of viscosity.

Eliminating p from (2.1) and (2.2), we have

$$\Delta\omega=0, \quad (2.4)$$

where ω is the vorticity defined by

$$\omega = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}. \quad (2.5)$$

Introducing the stream function Ψ defined as

$$u = \frac{\partial \Psi}{\partial y}, \quad v = -\frac{\partial \Psi}{\partial x}, \quad (2.6)$$

we can rewrite (2.5) in the form

$$\Delta\Psi = -\omega. \quad (2.7)$$

We consider the flow past a lattice of parallel equal and equidistant flat plates with-

Fig. 1. Configuration of a lattice of flat plates in a uniform flow.

out stagger placed parallel to the uniform flow (Fig. 1). Then, the boundary conditions for ω and Ψ are as follows:

$$\omega=0 \quad \text{for } y=0, |x|>1, \quad (2.8a)$$

$$\omega=g(x) \quad \text{for } y=0, |x|\leq 1, \quad (2.8b)$$

$$\omega=0 \quad \text{for } y=h/2, \quad (2.8c)$$

$$\phi=0 \quad \text{for } y=0, h/2, \quad (2.8d)$$

$$\partial\phi/\partial y = -U \quad \text{for } y=0, |x|<1, \quad (2.8e)$$

where $g(x)$ is an unknown function, ϕ is a perturbation stream function defined as $\Psi = Uy + \phi$, and U is the undisturbed flow velocity.

We define the Fourier transform and the inverse Fourier transform of $f(x, y)$ as

$$f^*(\alpha, y) = \int_{-\infty}^{\infty} f(x, y) e^{-i\alpha x} dx, \quad (2.9a)$$

$$f(x, y) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f^*(\alpha, y) e^{i\alpha x} d\alpha. \quad (2.9b)$$

Then, we can transform (2.4) and (2.7) as follows;

$$\frac{d^2\omega^*}{dy^2} - \alpha^2\omega^* = 0, \quad (2.10)$$

$$\frac{d^2\phi^*}{dy^2} - \alpha^2\phi^* = -\omega^*. \quad (2.11)$$

Also, the boundary conditions (2.8) become

$$\omega^* = g^*(\alpha) \equiv \int_{-1}^1 g(x) e^{-i\alpha x} dx \quad \text{for } y=0, \quad (2.12a)$$

$$\omega^* = 0 \quad \text{for } y=h/2 \quad (2.12b)$$

$$\phi^* = 0 \quad \text{for } y=0, h/2 \quad (2.12c)$$

Solving (2.10) subject to the boundary conditions (2.12a) and (2.12b), we obtain

$$\omega^*(\alpha, y) = \frac{\sinh \alpha(h-y)}{\sinh(\alpha h/2)} g^*(\alpha). \quad (2.13)$$

Substituting (2.13) into (2.11) and solving (2.11) subject to the condition (2.12c), we have

$$\phi^*(\alpha, y) = \frac{g^*(\alpha)}{4\alpha \sinh^2(\alpha h/2)} \{y \sinh \alpha(h-y) - (h-y) \sinh \alpha y\}. \quad (2.14)$$

In order to obtain $\phi(x, y)$ from (2.14), we make use of the convolution theorem, that is,

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} f^*(\alpha) h^*(\alpha) e^{i\alpha x} d\alpha = \int_{-\infty}^{\infty} f(p) h(x-p) dp. \quad (2.15)$$

Thus, we have

$$\phi(x, y) = \frac{1}{2\pi} \int_{-\infty}^{\infty} g^*(\alpha) K^*(\alpha, y) e^{i\alpha x} d\alpha = \int_{-\infty}^{\infty} g(p) K(x-p, y) dp, \quad (2.16)$$

where

$$K^*(\alpha, y) = \frac{1}{4\alpha \sinh^2(\alpha h/2)} \{y \sinh \alpha(h-y) - (h-y) \sinh \alpha y\}, \quad (2.17)$$

and

$$K(x, y) = \frac{1}{2\pi} \int_{-\infty}^{\infty} K^*(\alpha, y) e^{i\alpha x} d\alpha. \quad (2.18)$$

By use of the method of contour integral, we can evaluate the integral of (2.18). The contours are such as shown in Fig. 2. Residues of $K^*(\alpha) e^{i\alpha x}$ are

$$R_n = \frac{ie^{-(2\pi n/h)x}}{2\pi n h} \cdot \left(\frac{h}{2\pi n} + x \right) \times \left\{ y \sinh \frac{2\pi n}{h} (h-y) - (h-y) \sinh \left(\frac{2\pi n}{h} y \right) \right\},$$

at $\alpha = i \frac{2\pi n}{h} \quad (n = \dots, -2, -1, 1, 2, \dots).$

(2.19)

It is to be noted that the singularity at $\alpha=0$ is a removable one.

Now, $K(x)$ expressed as the contour integral consists of the sum of residues corresponding to the singularities enclosed in the contour and a contribution from the integral over the semi-circle, whose radius R is to be taken as infinite. It can be easily verified that the latter contribution vanishes by making $R \rightarrow \infty$. Then, we can express the contour integral as follows:

$$K(x) = \begin{cases} i \sum_{n=1}^{\infty} R_n & \text{for } x \geq 0, \\ -i \sum_{n=1}^{\infty} R_{-n} & \text{for } x \leq 0, \end{cases} \quad (2.20)$$

which becomes, by (2.19),

$$K(x) = -\frac{1}{2\pi h} \sum_{n=1}^{\infty} \frac{1}{n} \left(\frac{h}{2\pi n} + |x| \right) e^{-(2\pi n/h)|x|} \left\{ y \sinh \frac{2\pi n}{h} (h-y) - (h-y) \sinh \frac{2\pi n}{h} y \right\}. \quad (2.21)$$

Hence (2.16) becomes

$$\phi(x, y) = -\frac{1}{2\pi h} \int_{-1}^1 g(p) \sum_{n=1}^{\infty} \frac{1}{n} \left(\frac{h}{2\pi n} + |x-p| \right) e^{-(2\pi n/h)|x-p|} \times \left\{ y \sinh \frac{2\pi n}{h} (h-y) - (h-y) \sinh \frac{2\pi n}{h} y \right\} dp. \quad (2.22)$$

Now, we have

$$\left. \frac{\partial \phi}{\partial y} \right|_{y=0} = \frac{1}{h} \int_{-1}^1 g(p) \left\{ -\frac{h}{2\pi} \ln (1 - e^{-(2\pi/h)|x-p|}) + |x-p| \frac{e^{-(2\pi/h)|x-p|}}{1 - e^{-(2\pi/h)|x-p|}} \right\} dp. \quad (2.23)$$

Thus, the boundary condition (2.8e) gives

$$2\pi U = \int_{-1}^1 g(p) \left\{ \ln (1 - e^{-(2\pi/h)|x-p|}) + \frac{2\pi}{h} |x-p| \frac{e^{-(2\pi/h)|x-p|}}{1 - e^{-(2\pi/h)|x-p|}} \right\} dp \quad \text{for } |x| < 1, \quad (2.24)$$

Fig. 2. Contours used for the evaluation of the integral (2.18). (a) is used in case of $x \geq 0$ and (b) in case of $x \leq 0$.

which is the Fredholm integral equation of the first kind with respect to the vorticity $g(x)$ on the flat plate. This forms the basic equation for the subsequent treatment of our problem.

§ 3. Asymptotic Solution when $2\pi/h \rightarrow 0$

In case when $2\pi/h \ll 1$, we can expand the kernel of the integral equation (2.24) as follows:

$$\ln(1 - e^{-(2\pi/h)|x-p|}) - \frac{2\pi}{h}|x-p| \frac{e^{-(2\pi/h)|x-p|}}{1 - e^{-(2\pi/h)|x-p|}} = \ln \frac{2\pi}{h} - 1 + \ln |\cos \alpha - \cos \beta| - \frac{1}{24} \left(\frac{2\pi}{h} \right)^2 (\cos \alpha - \cos \beta)^2 + \frac{1}{960} \left(\frac{2\pi}{h} \right)^4 (\cos \alpha - \cos \beta)^4 + \dots, \quad (3.1)$$

where we have put

$$x = \cos \alpha, \quad p = -\cos \beta, \quad (3.2)$$

In view of the form of (3.1), let us write

$$g(\cos \beta) \sin \beta = \sum_{n=0}^{\infty} \left(\frac{2\pi}{h} \right)^{2n} \varphi_n(\beta). \quad (3.3)$$

Substituting (3.1) and (3.3) into (2.24) and equating terms of the order $(2\pi/h)^{2n}$ on both sides (where $n=0, 1, 2, \dots$), we have series of integral equations

$$\int_0^\pi \varphi_0(\beta) \left(-P - \sum_{m=1}^{\infty} \frac{2}{m} \cos m\alpha \cos m\beta \right) d\beta = 2\pi U, \quad (3.4)$$

$$\int_0^\pi \left\{ \varphi_1(\beta) \left(-P - \sum_{m=1}^{\infty} \frac{2}{m} \cos m\alpha \cos m\beta \right) - \frac{1}{24} \varphi_0(\beta) (\cos \alpha - \cos \beta)^2 \right\} d\beta = 0, \quad (3.5)$$

$$\int_0^\pi \left\{ \varphi_2(\beta) \left(-P - \sum_{m=1}^{\infty} \frac{2}{m} \cos m\alpha \cos m\beta \right) - \frac{1}{24} \varphi_1(\beta) (\cos \alpha - \cos \beta)^2 + \frac{1}{960} \varphi_0(\beta) (\cos \alpha - \cos \beta)^4 \right\} d\beta = 0, \quad (3.6)$$

and so on, where

$$P = 1 - \ln(\pi/h), \quad (3.7)$$

and we have used the formula

$$\ln |\cos \alpha - \cos \beta| = - \sum_{m=1}^{\infty} \frac{2}{m} \cos m\alpha \cos m\beta - \ln 2.$$

Let us assume

$$\varphi_n(\alpha) = \sum_{m=0}^{\infty} c_{nm} \cos 2m\alpha. \quad (3.8)$$

Then, substituting (3.8) into (3.4), we can determine c_{0m} :

$$c_{00} = -2U/P, \quad c_{01} = c_{02} = c_{03} = \dots = 0, \quad (3.9)$$

so that we have

$$\varphi_0(\alpha) = -2U/P. \quad (3.10)$$

In quite a similar manner, we can obtain

$$\varphi_1(\alpha) = \frac{1}{12} \frac{U}{P^2} (1 + P \cos 2\alpha), \quad (3.11)$$

$$\varphi_2(\alpha) = -\frac{1}{288} \frac{U}{P^2} \left\{ 1 + \frac{8}{5} + P \left(1 + \frac{12}{5} P \right) \cos 2\alpha - \frac{3}{10} \cos 4\alpha \right\}, \quad (3.12)$$

and so on.

The drag D of the flat plate is determined by

$$\begin{aligned} D &= -2\mu \int_{-1}^1 g(x) dx = -2\mu \int_0^\pi \sum_{n=0}^{\infty} \left(\frac{2\pi}{h} \right)^{2n} \varphi_n(\alpha) d\alpha \\ &= 4\pi\mu \frac{U}{P} \left\{ 1 - \frac{1}{24} \left(\frac{2\pi}{h} \right)^2 \frac{1}{P} + \frac{1}{576} \left(\frac{2\pi}{h} \right)^4 \frac{1}{P} \left(1 + \frac{8}{5} P \right) + \dots \right\}, \end{aligned} \quad (3.13)$$

and the drag coefficient C_D by

$$C_D \equiv \frac{D}{\frac{1}{2}\rho U^2 \cdot 2} = \frac{8\pi}{R} \frac{1}{P} \left\{ 1 - \frac{1}{24} \left(\frac{2\pi}{h} \right)^2 \frac{1}{P} + \frac{1}{576} \left(\frac{2\pi}{h} \right)^4 \frac{1}{P} \left(1 + \frac{8}{5} P \right) + \dots \right\} \quad (3.14)$$

where

$$R = \frac{2U\rho}{\mu} \quad (3.15)$$

is the Reynolds number based on the breadth of the flat plate. It should be noted that the formulae (3.13) and (3.14) are valid only for the case $P > 0$, and hence by (3.7), for $h > \pi/e = 1.1557 \dots$.

§ 4. Asymptotic Solution when $2\pi/h \rightarrow \infty$

In order to solve (2.24) when $2\pi/h \gg 1$, we put

$$\xi = bx, \quad \eta = bp \quad (b = 2\pi/h). \quad (4.1)$$

Substituting (4.1) into (2.24), we have

$$2\pi b U = \int_{-b}^b g(\eta) \left\{ \ln(1 - e^{-|\xi-\eta|}) - |\xi-\eta| \frac{e^{-|\xi-\eta|}}{1 - e^{-|\xi-\eta|}} \right\} d\eta. \quad (4.2)$$

Taking into account the fact that $b \gg 1$ and that the kernel is singular at $\xi = \eta$, we may write (4.2) approximately in the form

$$2\pi b U = 2g(\xi) \int_0^\infty \left\{ \ln(1 - e^{-\eta}) - \eta \frac{e^{-\eta}}{1 - e^{-\eta}} \right\} d\eta = -\frac{2\pi^2}{3} g(\xi). \quad (4.3)$$

Then we have

$$g(x) = -\frac{6U}{h} \quad (4.4)$$

so that the tangential stress τ on the flat plate is

$$\tau = -\mu g(x) = \frac{6\mu U}{h}. \quad (4.5)$$

We can obtain the drag and the drag coefficient of the flat plate in the same way as (3.13) and (3.14)

$$D_0 = \frac{24\mu U}{h}, \quad (4.6)$$

$$C_{D0} = \frac{48}{R} \frac{1}{h}. \quad (4.7)$$

Let us now consider the plane Poiseuille flow in a channel of breadth h with total flux Uh . In this case the vorticity ω and the stress τ on the walls of the channel can be readily calculated as

$$\omega = -\frac{6U}{h} \quad \text{and} \quad \tau = \frac{6\mu U}{h}. \quad (4.8)$$

These coincide with (4.4) and (4.5). This should naturally be expected, in view of the fact that the flow between the flat plates approaches the plane Poiseuille flow when h becomes small, except in the immediate neighbourhood of the leading and the trailing edges.

Next, we shall investigate the edge effect on the vorticity distribution $g(x)$. To this end, we put

$$\xi = b(x+1), \quad \eta = b(x+1), \quad (b=2\pi/h). \quad (4.9)$$

Then, we can transform (2.24) as

$$2\pi bU = \int_0^\infty g(\eta) \left\{ \ln(1 - e^{-|\xi-\eta|}) - |\xi-\eta| \frac{e^{-|\xi-\eta|}}{1 - e^{-|\xi-\eta|}} \right\}, \quad (4.10)$$

by considering that $b \gg 1$. (4.10) is an integral equation of the Wiener-Hopf type.

In order to solve (4.10), we put

$$\frac{1}{2\pi} \int_0^\infty g(\eta) \left\{ \ln(1 - e^{-|\xi-\eta|}) - |\xi-\eta| \frac{e^{-|\xi-\eta|}}{1 - e^{-|\xi-\eta|}} \right\} d\eta = \begin{cases} bUe^{-\alpha\xi} & \text{for } \xi > 0, \\ h(\xi) & \text{for } \xi < 0, \end{cases} \quad (4.11)$$

where α is a small positive parameter to be made 0 in the limit. We apply the Fourier transformation to (4.11) as shown in (2.9). Then, (4.11) becomes

$$\frac{1}{2} g^*(\zeta) \frac{1}{\zeta} \frac{\sinh 2\pi\zeta - 2\pi\zeta}{\cosh 2\pi\zeta - 1} = h^*(\zeta) + \frac{bU}{\alpha + i\zeta}, \quad (4.12)$$

by using

$$\int_{-\infty}^\infty \left\{ \ln(1 - e^{-|\eta|}) - |\eta| \frac{e^{-|\eta|}}{1 - e^{-|\eta|}} \right\} e^{-i\zeta\eta} d\eta = \frac{\pi}{\zeta} \frac{\sinh 2\pi\zeta - 2\pi\zeta}{\cosh 2\pi\zeta - 1}. \quad (4.13)$$

We shall consider the region where ξ is large. This corresponds to the small value of $|\zeta|$, and hence we can expand (4.13) as follows:

$$\frac{\sinh 2\pi\zeta - 2\pi\zeta}{\cosh 2\pi\zeta - 1} = \frac{2\pi}{\zeta} \frac{1 + (1/20)(2\pi\zeta)^2 + (1/840)(2\pi\zeta)^4 + \dots}{1 + (1/12)(2\pi\zeta)^2 + (1/360)(2\pi\zeta)^4 + \dots}. \quad (4.14)$$

As a first approximation, we retain only the first two terms in the denominator and the numerator in (4.14), so that (4.11) becomes

$$\frac{\pi}{5} g^*(\zeta) \frac{\zeta^2 + 5/\pi^2}{\zeta^2 + 3/\pi^2} = h^*(\alpha) - \frac{ibU}{\zeta - i\alpha}. \quad (4.15)$$

Noting that $g^*(\zeta)$ is regular in the lower half of the complex ζ -plane and $h^*(\zeta)$ is regular in the upper half plane, we may rewrite (4.15) as

$$\begin{aligned} \frac{\pi}{2} g^*(\zeta) \frac{\zeta - i\sqrt{5}/\pi}{\zeta - i\sqrt{3}/\pi} + \frac{ibU}{\zeta - i\alpha} \frac{\alpha + \sqrt{3}/\pi}{\alpha + \sqrt{5}/\pi} \\ = \frac{\zeta + i\sqrt{3}/\pi}{\zeta + i\sqrt{5}/\pi} h^*(\zeta) - \frac{ibU}{\zeta - i\alpha} \left(\frac{\zeta + i\sqrt{3}/\pi}{\zeta + i\sqrt{5}/\pi} - \frac{\alpha + \sqrt{3}/\pi}{\alpha + \sqrt{5}/\pi} \right). \end{aligned} \quad (4.16)$$

The left-hand side is regular in the lower half plane and the right-hand side is regular in

the upper half plane. Therefore, both sides should be regular in the whole ζ -plane, and hence, equal to a constant. It can be readily shown that the constant is zero. $g^*(\zeta)$ being thus found, we can determine $g(\xi)$:

$$\begin{aligned} g(\xi) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} g^*(\zeta) e^{i\xi\zeta} d\zeta = -\frac{2\sqrt{15}U}{h} \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{p+\sqrt{3}/\pi}{p(p+\sqrt{5}/\pi)} e^{\xi p} dp \\ &= -\frac{6U}{h} \left(1 + \frac{\sqrt{5}-\sqrt{3}}{\sqrt{3}} e^{-(2\sqrt{5}/h)(x+1)} \right), \end{aligned} \tag{4.17}$$

where we have used the formula

$$\frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{\lambda p + \mu}{p(p+\beta)} e^{\xi p} dp = \frac{\mu}{\beta} + \frac{\beta\lambda - \mu}{\beta} e^{-\beta\xi}.$$

If we let x tend to infinity, (4.17) agrees with (4.4) which corresponds to the case of the plane Poiseuille flow. The second term in the bracket is a correction term due to the edge effect, which we shall write in the form:

$$g_1(x) = -\frac{6U}{h} \frac{\sqrt{5}-\sqrt{3}}{\sqrt{3}} e^{-(2\sqrt{5}/h)(x+1)}.$$

The correction D_1 to the drag is obtained as follows:

$$D_1 = -4\mu \int_{-1}^{\infty} g_1 dx = \frac{24\mu U}{h} \frac{\sqrt{5}-\sqrt{3}}{2\sqrt{15}}.$$

The drag coefficient becomes

$$C_D = \frac{D_0 + D_1}{\frac{1}{2}\rho U^2 \cdot 2} = \frac{48}{R} \frac{1}{h} \left(1 + \frac{\sqrt{5}-\sqrt{3}}{2\sqrt{15}} h \right).$$

In the second approximation, we retain the first three terms in (4.14). In quite a similar manner to the first approximation, we obtain the correction terms g_2 and D_2 for the vorticity $g(x)$ and the drag as

$$g_2(x) = -\frac{6U}{h} \{ A \cos a_1(x+1) + B \sin a_1(x+1) \} e^{-a_2(x+1)},$$

Table I. Calculated values of RC_D for various values of h .

I_0 is calculated by (4.7), II_0 by (4.21) and III_0 by (4.26).

$$D_2 = \frac{24\mu U}{h} \frac{h}{\sqrt{180}} \{(\sqrt{840} - 21)^{1/2} - (\sqrt{360} - 15)^{1/2}\}, \quad (4.23)$$

where

$$A = \sqrt{7/3} - 1, \quad B = (\sqrt{840} - 21)^{-1/2} \{(\sqrt{7/3} - 1)(\sqrt{840} + 21)^{1/2} - 2\sqrt{7/3}(\sqrt{360} + 15)^{1/2}\}, \quad (4.24)$$

$$a_1 = \frac{1}{\sqrt{2}h} (\sqrt{840} - 21)^{1/2}, \quad a_2 = \frac{1}{\sqrt{2}h} (\sqrt{840} + 21)^{1/2}, \quad (4.25)$$

and the drag coefficient becomes

$$C_D = \frac{D_0 + D_2}{\frac{1}{2}\rho U^2 \cdot 2} = \frac{48}{R} \frac{1}{h} \left[1 + \frac{h}{\sqrt{180}} \{(\sqrt{840} + 21)^{1/2} - (\sqrt{360} + 15)^{1/2}\} \right]. \quad (4.26)$$

§ 5. Numerical Discussions

The drag coefficient is inversely proportional to the Reynolds number as is natural in the Stokes approximation. Thus, RC_D is a function of h only. Fig. 3 and Table I show the numerical values of RC_D for the various values of h .

Fig. 3.

The asymptotic solution (3.14) corresponding to $h \rightarrow \infty$ can be used only for $h < \pi/e \approx 1.1557 \dots$. However, it seems that RC_D obtained from this asymptotic solution is correct within several per cent in the range $h = 5 \sim \infty$ in the third approximation in which $O(h^{-4})$ is retained. It appears that the

asymptotic solution corresponding to $h \rightarrow 0$ would give under-estimated value of RC_D . But the matching of both asymptotic solution seems to be satisfactory.

Acknowledgement

The author wishes to express his sincere thanks to Professor Isao Imai for his suggestion of this problem and continual guidance throughout this study. He is also indebted to Professor Hidenori Hasimoto for his advice and discussions and Dr. Mitutosi Kawaguti and Mr. Hideo Takami for their invaluable discussions.

Deviation from Linearity of the Concentration Dependence of the Molecular Sound Velocity in Liquid Mixtures

By Otohiko NOMOTO

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received August 18, 1958)

Accuracy of the linear dependence of the molecular sound velocity on the molar fractions of the component liquids was investigated in about 100 binary mixtures, employing existing ultrasonic data. The linearity proved to hold true within an accuracy of 0.3% for mixtures of two hydrocarbons or two monovalent alcohols, among others, while the deviation from linearity was larger (0.3%–4%) for the following mixtures: the aqueous solutions, mixtures containing one heavy component such as carbon tetrachloride or chloroform with light partners, mixtures containing glycerine, glycol, aniline, acetone, nitrobenzene, etc. The molecular compressibility (of Wada) showed a similar tendency, though the deviation from linearity was somewhat smaller than that of the molecular sound velocity, especially in case of the mixtures consisting of two component liquids of widely different densities.

§ 1. Introduction

It has been pointed out in a previous paper¹⁾ that Rao's molecular sound velocity²⁾ in liquid mixture

$$R = \frac{M}{\rho} V^{1/3} = v V^{1/3} \quad (1.1)$$

is approximately a linear function of the molar fraction n_A , n_B of the component liquids:

$$R = n_A R_A + n_B R_B = R_A + n_B (R_B - R_A), \quad (1.2)$$

where V means the sound velocity, ρ the density, v the molar volume, and

$$M = n_A M_A + n_B M_B \quad (1.3)$$

means the average molecular weight of the mixture. The quantities with suffixes A , B , refer to the component liquids A and B , respectively.

About 40 liquid mixtures were examined previously, and the linear relation was found to hold true except for the aqueous solutions and the mixtures consisting of one heavy component liquid such as carbon tetrachloride or chloroform with a light partner.

The linear relationship holds true also for aqueous sugar solutions and aqueous polyalcohol solutions³⁾, within the range of the concentrations investigated.

Although the relation (1.2) has not found any theoretical explanation as yet, it seems rather striking that such a simple relationship exists between v and V (or ρ and V), considering the rather complicated dependence of

V (or ρ) on concentration in some mixtures, even exhibiting maximum or minimum in some cases. So it seems worth while to investigate the deviation from linearity of the molecular sound velocity in detail.

§ 2. Deviation from Linearity of the Molecular Sound Velocity vs. Molar fraction in Binary Liquid Mixtures

Molecular sound velocity was computed for about 60 liquid mixtures in dependence on concentration by employing the existing ultrasonic data⁴⁾⁻¹¹⁾ and compared with the value computed from the linear formula (1.2). The result is summarized in Table I, together with the results on about 40 liquid mixtures, for which the molecular sound velocity was investigated in the previous paper¹⁾. For example, the mixture numbered as I-20 refers to the No. 20 mixture in the previous paper. (cf. the references in the previous paper for the sources of ultrasonic data for these first group of mixtures). Some of the mixtures reported in the previous paper were reinvestigated employing new ultrasonic data.^{4), 6), 7)}

In this table, ΔR means

$$\Delta R = R_{\text{cal}} - R_{\text{exp}}, \quad (2.1)$$

where R_{cal} is the value computed by (1.2) and R_{exp} the value computed by employing the sound velocity and density of the mixture.

In many of the cases, the molecular compressibility introduced by Wada¹²⁾

$$W = v\beta^{-1/7} \quad (2.2)$$

was also computed and the deviation

$$\Delta W = W_{\text{cal}} - W_{\text{exp}} \quad (2.3)$$

was obtained. Here W_{exp} is the value computed by employing the velocity and density data of the mixture and W_{cal} is the value corresponding to the linear formula:

$$W_{\text{cal}} = n_A W_A + n_B W_B. \quad (2.4)$$

The table indicates the maximum percentage deviations of R and W as the concentration is varied. For example, $\Delta R/R = 0.1\%$ means that the deviation is always positive, and that the maximum deviation is 0.1% , while $\Delta R/R = -0.1\%$ means that the deviation is always negative, the maximum deviation being -0.1% . On the other hand, $\Delta R/R = \pm 0.1\%$ means that the deviation assumes both positive and negative values, though the positive deviation is the greater, the maximum being 0.1% . $\Delta R/R = \mp 0.1\%$ means, on the contrary, that the negative deviation is the greater, the maximum being -0.1% .

The percentage deviation of R and W indicated in the table contain, naturally, also the experimental errors of V , ρ and n_B , so that the actual deviations may be some what smaller or larger than the tabular values.

§ 3. Result

We see that the deviation is comparatively large in the following mixtures;

(a) Aqueous solutions

(I-1~I-6, 45~49)

$\Delta R/R$ max. 3.7% (water-sulfuric acid)
max. -2.7% (water-ethanol)
min. -0.9% (water-formic acid).

(b) Mixtures containing one heavy component with a light partner

CCl_4 -mixtures (I-13, I-17, I-24, I-25, I-26, I-36, 58)

max. $\Delta R/R = 2.3\%$, $\Delta W/W = 1.2\%$ (tetralin-carbon tetrachloride)

CHCl_3 -mixtures (I-16, I-28, I-37, 19, 51)

max. $\Delta R/R = 2.8\%$, $\Delta W/W = 1.7\%$ (chloroform-ether)
min. $\Delta R/R = \pm 0.3\%$ (nitrobenzene-chloroform)

CH_2Cl_2 -mixtures (I-15, I-34)

max. $\Delta R/R = 0.6\%$, $\Delta W/W = 0.6\%$ (heptane-dichloromethane)
min. $\Delta R/R = 0.5\%$, $\Delta W/W = 0.3\%$ (benzene-dichloromethane)

(c) Mixtures containing glycerine, aniline, nitrobenzene, glycol

glycerine mixtures (39~45)

$\Delta R/R = 2.2 \sim 2.7\%$

aniline mixtures (I-9, I-32, 16, 17, 18, 51, 52)

max. $\Delta R/R = 1.4\%$ (chloroform-aniline)

mix. $\Delta R/R = 1.3\%$, $\Delta W/W = 0.63\%$ (aniline-ether)

nitrobenzene mixtures (I-7, I-8, I-14, I-32, 19, 53, 57)

max. $\Delta R/R = 2.2\%$, $\Delta W/W = 1.8\%$ (nitrobenzene-methanol)

min. $\Delta R/R = \pm 0.3\%$ (nitrobenzene-chloroform)

$\Delta R/R = \pm 0.25\%$, $\Delta W/W = \pm 0.8\%$ (nitrobenzene-toluene)

glycol mixtures (29~38)

max. $\Delta R/R = \mp 1.5\%$, $\Delta W/W = \mp 1.6\%$ (methanol-glycol)

min. $\Delta R/R = 0.3\%$ (glycerine-glycol)

On the other hand, the deviation is small in the mixtures:

(d) Mixtures of two hydrocarbons (I-20, I-21, 1~14, 54, 55, 60), for which

$\Delta R/R$ is usually smaller than 0.3% , except hexane-paraffin oil ($\pm 1.3\%$), isooctane-cyclohexane (-0.4%), pentane-heptane ($\mp 0.35\%$) and hexane-diphenyl methane (2.1%).

(e) Mixtures of two monovalent alcohols (20~28, 56), for which

$\Delta R/R \leq 0.3\%$, except methanol-dodecyl alcohol mixture (0.4%).

Although there is no theoretical explanation for the approximate linearity of the molecular sound velocity *vs.* molar fractions in binary mixtures, the fact that the linearity is most satisfactory in the mixtures consisting of two hydrocarbons and those of two monovalent alcohols seems to indicate that the deviation from linearity in other mixtures are due to the change in association of the liquids, at least to some extent. The effect of association is presumably great in case of aqueous solutions (cf. Nomoto¹³). On the other hand, the cause of deviation from linearity in class (b) mixtures (one heavy component and a light partner) is mainly due to the density effect, as pointed out in a previous paper¹. In this case the linearity of Wada's molecular compressibility is far better than that of the molecular sound velocity.

We may conclude, that the molecular sound

velocity in binary liquid mixtures is a linearly dependent quantity on the molar fractions of the component liquids in case there is no association, or in case the degree of association does not change with concentration, as long as the density of the component liquids are not so widely different each other.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN VOL. 13 No. 12 DECEMBER 1958

Empirical Formula for Sound Velocity in Liquid Mixtures

By Otohiko NOMOTO

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received August 18, 1958)

An empirical formula $V=(R/v)^3=\{(n_A R_A+n_B R_B)/(n_A v_A+n_B v_B)\}^3$, was derived for the sound velocity in binary liquid mixtures consisting of two component liquids *A* and *B*, on the assumption of the linear dependence of the molecular sound velocity $R=vV^{1/3}$ (v =molar volume and V =sound velocity) on concentration (molar fractions n_A , n_B) and the additivity of the molar volume. The suffixed quantities correspond to the component liquids. This formula holds true for such mixtures for which the linearity of the molecular sound velocity and the additivity of the molar volume is comparatively good, the mixtures of two hydrocarbons and those of two monovalent alcohols being the examples. The values of the empirical sound velocity were compared with those calculated by this formula for 38 mixtures with comparatively small values of the percentage deviation from linearity of R , and 28 of them showed deviations not larger than 1% in V . Of the 31 liquid mixtures with $\Delta R/R \leq 0.3\%$, 5 showed deviations of V larger than 1%, 4 of them being the mixtures consisting of two component liquids of widely different molar volumes.

§ 1. Introduction

As the sound velocity in liquid mixtures is known to be a quantity which depends on concentration in a variety of manners according to the nature of each component liquids, it becomes of considerable interest and importance if we can establish a formula to

predict the sound velocity in liquid mixtures. This, however, is not an easy task considering of the various manners of the concentration dependency, even exhibiting maximum or minimum at certain concentrations in some cases. So it will become necessary to employ one formula for some mixtures and other

formulas for other mixtures, even if we succeed to obtain some approximate formulas to represent the sound velocity.

Some formulas have been proposed^{1),2),3)} for the sound velocity in liquid mixtures. Schaaffs¹⁾ considered the sound velocity in ideal solutions to be a linear function of the weight percentages of the mixtures. Natta and Baccaredda²⁾ showed that a better agreement with experiment is attained by the formula

$$V = \frac{1}{\left(\frac{1-p}{\rho_A V_A^2} + \frac{p}{\rho_B V_B^2} \right) \rho} \quad (1.1)$$

where ρ means the density and p the weight fraction of the liquid B . This formula is based on the assumption that the sound velocity is the same as in the case when the two component liquids are separated in two layers and the direction of propagation of the sound is perpendicular to the interface. The formula proposed by Danusso³⁾ for ideal mixtures

$$V = \frac{1}{\rho} \left(\frac{1-p}{\rho_A^2 V_A^2} + \frac{p}{\rho_B^2 V_B^2} \right)^{-1/2} \\ = \frac{1}{\rho} \left[\frac{1}{M} \left(\frac{n_A M_A}{\rho_A^2 V_A^2} + \frac{n_B M_B}{\rho_B^2 V_B^2} \right) \right]^{-1/2} \quad (1.2)$$

has been found to hold true for some mixtures, but not necessarily in others. Here

$$M = n_A M_A + n_B M_B \quad (1.3)$$

means the mean molecular weight of the mixture. The quantities with suffixes A and B mean the corresponding quantities for the component liquid A and B , respectively, and n_A and n_B are the molar fractions of the component liquids. The ideal mixture is defined here as the mixture without volume change. So we have additivity of the molar volume

$$v = n_A v_A + n_B v_B, \quad (1.4)$$

and the density becomes

$$\rho = \frac{M}{v} = \frac{n_A M_A + n_B M_B}{n_A v_A + n_B v_B}. \quad (1.5)$$

For non-ideal liquids, however, the formula (1.2) does not hold true no longer. Danusso⁴⁾ has investigated the deviation from ideal velocity formula of the sound velocity in many mixtures and obtained some results of interest, especially the approximate proportionality amongst the percentage deviations of the quantities V (sound velocity), v (molar volume) and B (=Danusso's molecular compressibility), defined as

$$B = v\beta, \quad (1.6)$$

where β means the adiabatic compressibility.

Poupko⁵⁾ has performed a theoretical analysis of the sound velocity based on Prigogine et al.'s theory of liquid mixtures^{6),7)} and derived the result

$$\Delta v/v = k(\Delta\beta/\beta) \quad (1.7)$$

where k is a constant for each mixture. This, however, furnishes only an order of magnitude explanation for the deviation from ideality of the molar volume and the adiabatic compressibility (or sound velocity).

§ 2. Additivity of the Molar Volume and Proposal of an Empirical Formula for Sound Velocity

The formula proposed here is based on the assumption of the linearity of the molecular sound velocity *vs.* molar fractions and the additivity of the molar volume in liquid mixtures. The deviation from linearity of the molecular sound velocity has been investigated in a previous paper⁸⁾ and it has been reported that some mixtures, especially the mixtures of two hydrocarbons and those of two monovalent alcohols, exhibit the linear dependency on concentration with an accuracy usually not exceeding 0.3%.

Now we investigated the additivity of the molar volume in those mixtures for which the deviation from linearity of the molecular sound velocity is small, and it was revealed that a great part of these mixtures has also a good additivity relationship of the molar volume. So we can establish an empirical formula for the sound velocity in liquid mixtures based on the assumption of the linearity of the molecular sound velocity

$$R = n_A R_A + n_B R_B \quad (2.1)$$

where

$$R = \frac{M}{\rho} V^{1/3} = v V^{1/3}. \quad (2.2)$$

and the additivity of the molar volume (1.3), namely

$$V = \left(\frac{R}{v} \right)^3 = \left(\frac{n_A R_A + n_B R_B}{n_A v_A + n_B v_B} \right)^3. \quad (2.3)$$

Table I summarizes the result on the percentage deviation of the sound velocity computed by this formula ($\Delta V/V$) together with the percentage deviations of R and the molar volume v , for those mixtures with compara-

Table I. Maximum percentage deviations of the molecular sound velocity (R), and the molar volume (v) from linearity in some liquid mixtures and the maximum percentage deviation of the sound velocity (V) from the empirical formula (2.3).

* In conventional unit, where the sound velocity is measured in m/sec, and the density in g/cm³.

deviations of V exceeding 1%. Of the 31 liquid mixtures with percentage deviation of the molecular sound velocity not exceeding 0.3%, only 5 showed deviations of V exceeding 1%, 4 of these being the mixtures consisting of two constituent liquids of widely different molar volume. (I-21, n-heptane-benzene (ratio of the molar volumes=1.646), 11. isooctane-cetane (1.765), 13. cetane-cyclohexane (2.695), 22. methanol-octyl alcohol (3.926)). A more striking example is the mixture cetane-benzene, which is not included in Table I. This mixture exhibits a minimum of sound velocity at an intermediate concentration, which cannot be derived from the empirical formula (2.3). The ratio of the molar volumes being 3.253, $\Delta R/R=0.2\%$, and $\Delta v/v=-0.5\%$, and the deviation of the sound velocity attains $\Delta V/V=3\%$, or $\Delta V=40$ m/sec.

These are the exceptional examples, and as the accuracy of good ultrasonic measure-

ments are of the order of 0.1%, while that of rough measurements are of the order of 0.5—1%, an approximate formula of this order of accuracy may be of practical use in some cases.

Fig. 3-5 illustrate for three mixtures the

Fig. 1. Sound velocity and density of carbon tetrachloride-chloroform mixtures in dependence on concentration.

computed and the empirical sound velocities as functions of the concentration. By the way, it was remarked that most of the liquid mixtures satisfying the empirical formula (2.3) show a rather similar dependence of V and ρ on concentration, Fig. 2 (methanol-dodecyl alcohol mixture) and Fig. 3 (cetane-decalin) being such examples.

Fig. 2. Sound velocity and density of methanol-dodecyl alcohol mixtures in dependence on concentration.

§ 3. An Alternative Formula

As the linearity of the molecular compressibility (of Wada⁹⁾)

$$W = \frac{M}{\rho} \beta^{-1/7} = \frac{M}{\rho^{6/7}} V^{2/7} \quad (3.1)$$

is somewhat better than the linearity of the molecular sound velocity, it is possible to make an empirical formula using this relation and assuming the additivity of the molar volume. The formula, however, becomes somewhat complicated, and numerical com-

putation of some examples revealed that the practical result is not so improved because of the increased stages of the numerical computation involved.

A convenient alternative method consists in employing the linearity of the quantity

$$N = \frac{M}{\rho^{5/6}} V^{1/3} = R \rho^{1/6} \quad (3.2)$$

which shows as good a linearity of concentration dependence as the molecular compressibility (of Wada) (cf. Nomoto¹⁰⁾), namely

$$N = n_A N_A + n_B N_B \quad (3.3)$$

This gives, together with the additivity of the molar volume (1.4), the velocity formula:

$$V = \frac{N^3}{M^{1/2} v^{5/2}} = \frac{(n_A N_A + n_B N_B)^3}{(n_A M_A + n_B M_B)^{1/2} (n_A v_A + n_B v_B)^{5/2}} \quad (3.4)$$

This formula, though somewhat better than the formula (2.3), is of the same order of accuracy with (2.3), and, therefore, not to be recommended because of the complexity.

Table II gives the sound velocity computed by this formula together with those computed by (2.3) and the empirical velocity data for the aniline-acetone mixture.

Condenser Microphones with Plastic Diaphragms for Airborne Ultrasonics, I

By Kiichiro MATSUZAWA

*Department of Physics, Faculty of Science and Literature,
Ehime University*

(Received August 30, 1958)

A study is made on various condenser microphones, each of which consists of a metallic back plate and a thin plastic film stretched over the back plate, being in direct touch with it at a number of points. The surface of the back plate has been roughened or provided with grooves, hollows or holes, while the external surface of the plastic film has been made conductive by metallizing it.

The microphones are calibrated in the frequency range 1.5~150 kc/s. A fair agreement is found between the classifications of the back plates according to the mechanical roughnesses of the surfaces and the classifications based upon the frequency responses of the microphones. It is shown that the microphones with the back plates having finely roughened surfaces can be considered as single resonance systems.

Detailed data are given, with which a microphone having a flat frequency response up to a desired high frequency below 150 kc/s can be easily constructed.

§ 1. Introduction

Microphones for airborne ultrasonics are mainly used in two fields of research, namely: small model experiment in architectural acoustics in which n times of audible frequencies must be used in one n th model, and the study of ultrasonic cry and hearing of insects and small animals in biology.

For a long time workers in the fields of airborne ultrasonics had been handicapped by the lack of suitable microphones. In 1948, I. Rudnick and M. N. Stein¹⁾ calibrated two Western Electric 640-AA condenser microphones up to 100 kc/s, and found the drop-off of the frequency responses at a rate of about 12 dB per octave above 15 kc/s. In 1950, D. R. Griffin²⁾ used a W. E. 640-AA microphone in conjunction with electric filters. To make the resultant frequency response flat against the drop-off of the frequency response of the microphone, he had to use the electric filters whose frequency response increased at the same rate as that of the microphone. The resultant frequency response thus obtained was roughly flat for 20~100 kc/s, but the response had some peaks and dips¹⁾ and the absolute sensitivity was low.

In 1954, W. Kuhl, G. R. Schodder and F. K. Schröder constructed microphones and trans-

mitters of the condenser type with plastic diaphragms for airborne ultrasonics and named them "transducers with solid dielectric"³⁾. Each of the transducers consisted of a metallic back plate and a thin plastic film stretched over the back plate, being in direct touch with it at a number of points.

Although the investigation of Kuhl *et al.* is very extensive with both microphones and

Fig. 1. Cross-section of the microphone (unit mm).

transmitters, yet their study is not sufficient with regard to both the roughnesses of various back plates and the mechanical pre-strains of the diaphragms. In this paper, a study is made on the microphones with back plates of different roughnesses and with various diaphragms under different pre-strains. Thus, detailed data are given, with which a microphone having a flat frequency response up to a desired high frequency below 150 kc/s can be easily constructed.

§ 2. Construction of Microphones

The construction of our microphones is shown schematically in Fig. 1. After having cleaned up a plastic film by ethyl alcohol, its periphery was glued to the front surface of a metal case, the external surface of the film was painted by Du Pont Silver Paste No. 4817

diluted by benzene to make conductive, and then, the film was clamped by a clamp-ring. A copper back plate was screwed to an ebonite base, inserting a washer between them. By fixing the metal case to the ebonite base, the surface of the back plate was pushed out beyond the front surface of the metal case through a distance δ , which was adjusted from 0.2 to 0.7 mm by using a washer of moderate thickness. So that the diaphragm was stretched tightly and was in direct touch with the back plate at a number of points as

Fig. 2. Principle of the condenser microphone.

Table I. List of back plates.

Classification based upon roughnesses of the surfaces		Symbols of back plates	Details of the roughnesses of the surfaces of the back plates
Group	Sub-group		
I	IA	IA-1	The mechanically flattened surface is given small roughness with a sand paper.
		IA-2	The mechanically flattened surface is finely scribed with a scriber and is smoothly polished with a sand paper.
		IA-3	The surface is provided with a shallow spiral groove of about 0.5 mm in width.
		IA-4	The mechanically flattened surface is lightly prickpunched with a distance of about 1 mm to make small dips with ring margins on the surface.
	IB	IBa-5	The mechanically flattened surface is provided with about 500 small hollows of about 0.25 mm in diameter and 0.1 mm in depth.
		IBa-6 IBa-7	The mechanically flattened surface is provided with about 300 small hollows of about 0.4 mm in diameter and 0.25 mm in depth.
		IBb-8	The mechanically flattened surface is provided with about 110 hollows of about 0.9 mm in diameter and 0.4 mm in depth.
	IIA	IIA-9	The surface is provided with a spiral groove of about 0.1 mm in depth and 1.5 mm in width.
II	IIB	IIB-10	The mechanically flattened surface is provided with four holes of 2 mm in diameter and 2 mm in depth.
		IIB-11	The surface of IIB-10 is prickpunched in the similar manner to IA-4.
		IIB-12	The holes of IIB-11 are drilled through and are packed with cotton wool.

shown in Fig. 2. Thus, the dielectric of the condenser consists not only of one solid material but of two layers, namely the plastic diaphragm and a layer of air. Under a sound pressure, a displacement of the diaphragm occurs, in consequence of which the electrostatic capacitance formed by the back plate and the metallic layer of the diaphragm is altered.

Fig. 3. Schematic cross-sections of back plates.

The 12 back plates used in our experiments are listed in Table I, and the schematic cross-sections of the back plates are also sketched in Fig. 3. As seen in Table I, the back plates may be divided into two groups based upon the mechanical roughnesses of the surfaces, namely: the back plates of group I having finely roughened surfaces and those of group II having ruggedly roughened surfaces. Each group is able to be classified into some sub-groups. The back plates of group I are classified into two sub-groups, namely: the back plates of group IA having uniformly roughened surfaces and those of group IB having surfaces composed of planes and many hollows. Further, the back plates of group IB are classified into two sub-groups, namely: the back plates of group IBa having surfaces with

smaller hollows and the back plate of group IBb having a surface with somewhat larger hollows. In Table I, the back plates of group IA and those of group IBa are arranged respectively in order of the mechanical fineness of the surfaces. On the other hand, the back plates of group II are classified into two sub-groups, namely: the back plate of group IIA having a uniformly roughened surface and those of group IIB having surfaces with large holes.

As diaphragms, films of polyethylene and polyester are used. The thickness of the film of polyethylene is about 20μ . For the films of polyester, Du Pont gauge 100, 50 and 25 Mylar and gauge 50 Metallized Mylar are used, the thicknesses being about 25, 13, 6 and 13μ respectively.

§ 3. Free-field Correction and Free-field Calibration

The free-field correction for normal incidence sound is defined as the difference between the free-field calibration for normal incidence and the pressure calibration.

An MR-103 condenser microphone, which is frequently used in our country in the audible frequency range, is provided with a metallic capsule so as to give the similar figure to our microphones. The effect of the capsule on the sensitivity in a free field is found to be merely about ± 1 dB even for 3~12 kc/s. On the other hand, the free-field correction of MR-103 condenser microphone may be estimated to be equal to that of a W. E. 640-AA microphone, which has been measured up to 100 kc/s⁽¹⁾, even for ultrasonics because of the identical dimensions.

Fig. 4. Free-field correction vs. frequency.

Based on the facts above mentioned, the free-field correction of our microphones is obtained as shown in Fig. 4.

Any two of our microphones are placed face to face at a certain distance and the one is used as a source and the other as a receiver. With this arrangement, linearity, spherical sound field and the reciprocity are examined

as follows.

- i) *Linearity* The perfectness of linearity of our microphones is ascertained by the proportionality between the current flowing through the source and the output voltage of the receiver.
- ii) *Spherical sound field* Spherical sound field is ascertained by the fact that the output

voltage of the receiver is proportional to the reciprocal of the distance between the source and the receiver.

iii) *Reciprocity* Two microphones are named *A* and *B* respectively, and both the ratio of the current through the microphone *A* operating as a source to the output voltage of *B* as a receiver and the ratio of the current through

the microphone *B* operating as a source to the output voltage of *A* as a receiver are measured. Thus, it is found that in any case these two ratios are equal to each other, and accordingly it is concluded that our microphones obey the reciprocity theorem.

Based on the three points above mentioned, our microphones can be calibrated according to the reciprocity method in a free field¹⁾. Thus, for the calibration of our microphones, the reciprocity method has been used for 10 ~150 kc/s, whereas in the frequency range 1.5~10 kc/s the method of comparison with the known sensitivity of the MR-103 microphone has been used. The straying of the sensitivities with the different calibrations are almost within ± 1.5 dB, and the difference in the sensitivities at 10 kc/s by the two methods is also within the errors of measurements. As an addendum, some of our microphones are calibrated up to 190 kc/s.

The sound absorption in air is not taken into account, because even at high frequencies the error in the sensitivity due to the absorption is less than 1 dB^{1), 4)}, which is of the same

order as the errors of measurements.

The polarizing voltage applied to our microphones is 200 volts in any case.

The self-noise of our microphones is less than that of a pre-amplifier.

§ 4. Stability

i) *Microphones with back plates of group I*

The stability of the frequency responses of our microphones with the back plates of group I are examined with regard to the following five points. And then the frequency responses are found to be stable.

1) *Temporal constancy* A temporal inconstancy of the sensitivity by the application of the polarizing voltage is inappreciable. Accordingly, the drop of the sensitivities due to the charging effect reported by Kuhl *et al.*³⁾ is small enough for our microphones.

2) *Long-time constancy* Three examples of the long-time variations in the sensitivities of our microphones are shown in Fig. 5. The straying of the sensitivities are within about 3 dB excepting the straying of 4~5 dB at 6, 8 and 60 kc/s in Fig. 5(a); at 4, 10, 130 and

Fig. 6. Frequency responses of microphones obtained by renewing the diaphragms of same microphones. Sensitivity in dB rel. 1V/ μ bar vs. frequency.

	Back plate	δ	Diaphragm
(a)	IA-2	0.3 mm	13 μ Polyester (Metallized Mylar)
(b)	IBb-8	0.63 mm	

140 kc/s in Fig. 5(b); and at 4, 4.5, 8, 9, 10, 11 and 60 kc/s in Fig. 5(c). The straying is, on the whole, only a little larger than the errors of measurements.

3) *Uniformity* The frequency responses in Fig. 5(b) and those in Fig. 5(c) show that the identical construction data (see the back plate IBa-6 and the back plate IBa-7 in Table I) give the similar responses.

4) *Reproducibility* To check the reproducibility of the frequency responses, some of our microphones are decomposed and are composed again by using new films of the same sorts as before. Two examples are shown in Fig. 6, the straying of the sensitivities by renewing 3 times the diaphragms is within 3 dB excepting the straying of about 4 dB at 40 and 150 kc/s in Fig. 6(a) and at 60 kc/s in Fig. 6(b). The straying is, on the whole, only a little larger than the errors or measurements. Accordingly the reproducibility is good. When the films other than the Metallized Mylar are used, as a matter of course, the reproducibility is not always good as shown in Fig. 6 because of the different surface densities of the metallic layers on the films painted by hand.

5) *Effect of humidity* Throughout our experiments, the effect of humidity upon the frequency responses of our microphones is inappreciable.

ii) *Microphones with back plates of group II*
The stability of the microphones with the back plates of group II is not examined because of uselessness of the microphones. The details will be mentioned in § 6.

§ 5. Effect of δ

i) *Microphones with back plates of group I*
The relation between the frequency responses and the amount δ, which has an effect on the mechanical pre-strains of the diaphragm, has been examined. When δ is less than 0.4 mm, the frequency responses of some microphones of group I are almost independent of δ. However, those of some others depend upon it, the sensitivities of the flat parts of the frequency responses decreasing with increasing δ and the cut-off frequencies increasing with increase of δ. Moreover, the dependences of the frequency responses on δ are altered by varying strains with which the films are initially glued to the metal cases.

	Diaphragm	
	Polyethylene	Polyester
$(Q)_{\delta=0.55}/(Q)_{\delta=0.4}$	1~1.1	0.8~1.2
$(f)_{\delta=0.55}/(f)_{\delta=0.4}$	1	1~1.08
$(S)_{\delta=0.55}-(S)_{\delta=0.4}$	0 dB	-2~0 dB (rarely -3 dB)

Fig. 7. Effect of δ upon frequency responses. Sensitivity in dB rel. 1V/μbar vs. frequency.

	Back plate	Diaphragm	
(a)	IA-2	13μ Polyester	} Δ δ=0.4 mm ▽ δ=0.55 mm
(b)	IA-4	20μ Polyethylene	
(c)	IBb-8	13μ Polyester	
(d)	IBb-8	20μ Polyethylene	

Next, the Q -factor, the resonance frequency f , and the low frequency sensitivity S for our microphones at $\delta=0.55$ mm and those for the same microphones at $\delta=0.4$ mm have been examined. The results of the measurements are given in Table II, and some examples of the effects of δ upon the frequency responses are shown in Fig. 7. The method of determination of Q , f and S for our microphones may be explained in § 6. As seen in Table II and Fig. 7, when δ is larger than 0.4 mm, the effects of δ for the microphones with the diaphragms of polyethylene are almost inappreciable and those of polyester are very little. Therefore, for each of our microphones, only the mean of the two frequency responses at $\delta=0.55$ mm and at $\delta=0.4$ mm may be given in § 6, i).

ii) Microphones with back plates of group II

The dependence upon δ of the frequency responses of our microphones of group II has not been examined because of their uselessness (§ 6).

§ 6. Dependence of Frequency Responses upon Back Plates and Diaphragms

i) Microphones with back plates of group I

The details of 20 microphones with the back plates of group I used in our experiments are shown in Table III. In the first, second and third columns there are shown the symbol of the back plate, the material of the diaphragm and the surface density M of the diaphragm with the metallic layer, respectively. In the fourth column there is shown the effective thickness d_e of the diaphragm, obtained by the measurement of the electrostatic capacitance of the film. In the fifth column there is shown the electrostatic capacitance of the microphone. For the shortness sake, the frequency responses of the microphones (a)~(g) denoted in the ninth column are shown representatively in Fig. 8.

Each of the theoretical frequency responses in Fig. 8 is obtained as follows. A theoretical pressure response of an ideal microphone, which is a single resonance system, is deter-

mined by three factors, namely: the Q -factor, the resonance frequency f and the low frequency sensitivity S . The theoretical free-field response of the ideal microphone is obtained by superposing the theoretical pressure response of the ideal microphone on the free-field correction shown in Fig. 4. Then, the three factors of the single resonance system are provided with suitable numerical values

so that the theoretical frequency response of the ideal microphone in a free field is in accord with the experimental frequency response. The suitable numerical values of the three factors are shown in the sixth, seventh and eighth columns of Table III. As shown in Fig. 8, the theoretical responses are in good agreement with the experiments excepting the small deviations for 4~7 kc/s and 13~20 kc/s, which might be caused by the systematic errors of measurements. The agreements between the theoretical responses and the experimental responses show that our microphones can be considered as the single resonance systems. The dependence of the three factors, namely, the Q -factor, the resonance frequency f and the low frequency sensitivity S , upon the back plates and the diaphragms are discussed in the following:

1) Q -factor

As shown in the first and sixth columns of Table III, the values of Q -factor for the microphones with the back plates of group IA are 2.0~3.3, while those for the microphones of group IB are 0.9~1.4. Accordingly, the sub-classification of the back plates of group I into IA and IB based upon the mechanical roughnesses of the surfaces is in accord with the classification based upon the values of Q .

2) Resonance frequency f

Values of the resonance frequency f and the surface density M as tabulated in Table III are shown graphically in Fig. 9(a), (b) and (c), on logarithmic scale.

From these figures it will be seen that for each of our microphones with the back plates IA-2, IA-3, IA-4, IBa-5 and IBa-7, there holds, within experimental error, a linear relationship given by $\ln f = \ln k - \frac{1}{2} \ln M$ where k is a constant. As will be explained in our subsequent paper⁵⁾, a similar relationship holds also for the back plate IA-1.

The existence of the relation $f = kM^{-1/2}$ for each of the above 6 back plates shows that, among various properties of the diaphragms, only the surface density M affects the resonance frequency f , thus showing that the diaphragm acts dynamically as a mass.

On the contrary, no such relationship holds for the back plate IBb-8, as can be seen from Fig. 9(c).

Thus, it is found that the sub-classification of the back plates of group IB into IBa and

Fig. 8. Frequency responses of microphones with back plates of group I, and theoretical responses corresponding to them. Sensitivity in dB rel. $1V/\mu\text{bar}$ vs. frequency.

● measurement
— theory

IBb based upon the mechanical roughnesses of the surfaces is in accord with the classification due to whether the relation $f = kM^{-1/2}$ holds good or not.

The order of the arrangement of the back plates of group IA in Table I, being the order

of the mechanical fineness of the surfaces, is in accord with the order of the straight lines from right to left in Fig. 9(a). Namely, the order agrees with the order of the values of k . Similar relations hold also for the back plates of group IBa.

3) Low frequency sensitivity S

Curves of the low frequency sensitivity S plotted against the effective thickness d_e in Table III are shown in Fig. 10. The values of S decrease with increasing values of d_e . A

Fig. 9. Surface density M in mg/cm^2 of diaphragm vs. resonance frequency f in kc/s .

Fig. 10. Low frequency sensitivity S in $\text{dB rel. } 1\text{V}/\mu\text{bar}$ vs. effective thickness d_e in μ of diaphragm.

similar relation holds between S and d_e for the back plate IA-1, as will be explained in our subsequent paper⁵⁾.

As shown in Fig. 10(a), except for the back plate IA-4, the order of the arrangement of the back plates of group IA in Table I is in accord with the increasing values of S for the same values of d_e . Similar relations hold also for the back plates of group IBa.

A microphone having a flat frequency response up to a desired high frequency below 150 kc/s can be easily constructed if we refer to Table I and Fig. 9. The sensitivity of the microphone can be estimated beforehand if we refer to Fig. 10.

ii) Microphones with back plates of group II

The frequency response of our microphone with the back plate of group IIA and those with the back plates of group IIB are shown in Fig. 11(a) and (b) respectively. The frequency response in Fig. 11(a) is similar to the theoretical response of the ideal microphone except for the large dips at 3 and 60 kc/s. The frequency responses in Fig. 11(b) are evidently different from the theoretical response of the ideal microphone because of the sharp dip at 50 kc/s for the back plate IIB-10,

also of the sharp dip at 40.5 kc/s for the back plate IIB-11 and of the large peak at about 3 kc/s as well as the large dip for 33~60 kc/s for the back plate IIB-12. Therefore the sub-classification of the back plates of group II into IIA and IIB based upon the mechanical roughnesses of the surfaces is in accord with the classification based upon the frequency responses.

Thus, the classifications of the back plates based upon the roughnesses of the surfaces shown in Table I are in accord with the classifications based upon the frequency responses.

§ 7. Conclusion

In the present paper, properties of condenser microphones with various back plates are studied in detail. The back plates used in the present experiment are divided into two groups I and II on the basis of the mechanical roughnesses of the surfaces and each of these two groups is further classified into some sub-groups as shown in Table I.

The frequency responses of our microphones with the back plates of group I are found to be equal to the theoretical frequency responses of the ideal microphones which are single resonance system. Accordingly, our microphones can be supposed to be single resonance systems. The Q -factor, the resonance frequency f and the low frequency sensitivity S of the single resonance system are then obtained for each of the measured frequency responses of our microphones.

It is found that for each of our microphones with the back plates of group IA and group IBa there exists a relation $f = kM^{-1/2}$ between the resonance frequency f and the surface density M , where k is a constant. This shows that the diaphragm of the microphone acts dynamically as a mass.

Next, the frequency responses of our microphones with the back plates of group II are found to be different from the theoretical frequency response of the ideal microphone because of some peaks and dips, so that those microphones are practically useless.

It is thus concluded that the classifications of the back plates based upon the mechanical roughnesses of the surfaces shown in Table I are in accord with the classifications based upon the frequency responses of the microphones with the back plates.

Fig. 11. Frequency responses of microphones with back plates of group II. Sensitivity in dB rel. $1V/\mu\text{bar}$ vs. frequency.

	Back plate	δ	Diaphragm
(a)	● IIA-9	0.4 mm	13μ Polyester
(b)	● IIB-10	"	"
	○ IIB-11	"	"
	△ IIB-12	"	"

The stability of the frequency responses of our microphones with the back plates of group I is studied on the five points: the temporal constancy, the long-time constancy, the uniformity, the reproducibility and the effect of humidity, and it is found that the frequency responses are stable.

The dependence of the frequency responses of our microphones with the back plates of group I upon δ , the push-out of the back plates, is examined, and it is found that they are almost independent of δ in case when $\delta \geq 0.4$ mm.

Summarising it may be concluded that a microphone having a flat frequency response up to a desired high frequency below 150 kc/s can be easily constructed if we refer to Table I and Fig. 9, and that the sensitivity of the microphone can be estimated beforehand if we refer to Fig. 10.

In conclusion, the writer wishes to express his cordial thanks to Professor S. Tomotika for his continual guidance and also for his kind inspection of the manuscript. The waiter's thanks are also due to Dr. O. Nomoto of the Kobayasi Institute of Physical Research for useful advice and discussions.

A Possible Mechanism of the Potential Variation of the Joshi Effect

By M. Venugopalan

Department of Chemistry, Banaras Hindu University, Banaras, India

(Received February 17, 1958)

The Joshi effect 1-6, an instantaneous and reversible photovariation of the discharge current i ($+\Delta i$, enhancement and $-\Delta i$, diminution) has been studied in a number of gases and vapours, elemental and compound^{3,7}, excited in Siemens' tube, G. M. Counter like semiozoniser^{3,8,9}, Geissler or Crooke's tube with internal metallic electrodes or (as in the so called electrodeless discharge) with external metallic sleeves¹⁰. The potential dependence¹¹ of $\pm\Delta i$, at constant intensity I and frequency ν of irradiation and for medium gas pressures p , is shown graphically in Fig. 1. The positive effect $+\Delta i$, the photoincrease of i , is small at low applied potentials V and increases initially with V to a maximum at $V + \Delta i$ max, identical with V_m , the threshold potential¹. Above this last, $+\Delta i$ decreases rapidly and changes to the negative effect $-\Delta i$, the photosuppression of i , at an inversion¹² potential $V_i I$. Beyond $V_i I$, $-\Delta i$ first increases rapidly, and diminishes slowly thereafter. A second inversion, $-\Delta i$ to $+\Delta i$, obtains, in certain systems¹³, at $V_j I$ in the region of high V ; this part of the curve is shown discontinuous in Fig. 1.

Fig. 1. Potential variation of the Joshi effect.

Various theories^{2,9,10,14-22} have been postulated from time to time to explain the above phenomenon on the assumption that $\pm\Delta i$ is either a volume effect or a surface phenomenon; however, the evidence for its surface origin is overwhelming. Of these Joshi's theory^{2,9,14}, which accounts for many of the observations as compared to others, contemplates (a) formation under discharge of an adsorption-like electrode layer consisting of excited

particles and ions and (b) characterised by a low work function ϕ ; (c) light releases electrons from this layer; (d) they are captured by the particles, whose electron affinity is enhanced by excitation under discharge to form negative ions (e) determined by the probability factor p/X (where p is the gas pressure and X , the applied electrical field); (f) the current decrease $-\Delta i$ is a space charge effect due to the formation of slow moving negative ions and also their much smaller ionizing efficiency compared with free electrons; (g) uncaptured photoelectrons and others, produced by their impact ionization under X , cause the positive effect $+\Delta i$ observed at low (and less often at large) V , which disfavour electron capture.

Based on the above theory, a possible explanation has been now offered by the author for the potential variation of $\pm\Delta i$, by considering in detail the nature of the adsorbed layer and specifying the conditions for the formation and stability of negative ions. It is as follows:

1. Ordinarily when a gas or vapour is enclosed in a reaction vessel (in the present case, the discharge space), there is an instantaneous uptake of the gas molecules on the interior surface of the reaction vessel. This is characterised by features of physical adsorption^{23,24} involving van der Waals' forces with very low heats of adsorption (1-5 kilocalories) and is always in dynamic equilibrium with the gas phase.

2. When a low electrical field is applied ($V \ll V_m$), the surface equilibrium is disturbed and when the activation energy (electrical) exceeds the heat of adsorption^{24,25}, electrical desorption of the layer occurs, resulting in a decrease in the surface work function ϕ and therefore, increased photoelectron emission causing $+\Delta i$, as shown by AB in Fig. 1. Evidence for this has been adduced from measurements of activation energies E and heats of activation $\Delta E^\ddagger$, for the adsorption²⁰ process responsible for $+\Delta i$. Such measurements showed that the magnitudes of E and $\Delta E^\ddagger$ are of the order of 5-6 and 4-5 kilocalories. The fact that this energy while excluding that resulting from electrical activation is not of the order of magnitude of activation energies in chemical reactions substantiates that the type of adsorption responsible for $+\Delta i$ is physical in nature.

3. (i). When the applied electrical field is enhanced progressively ($V \gg V_m$) activation energy (5-10 kilocalories) is available for the formation of a chemisorbed layer^{24,27}, and as this layer develops, ϕ increases resulting in a decreased photoelectron emission and hence $+\Delta i$ decreases, as shown by

BC in Fig. 1. (ii) This decrease in $+di$ becomes precipitous due to the cooccurrence of $-di$ at this stage, as a result of negative ion formation²⁸), determined by the probability factor p/X . Evidence for (i) has been obtained from measurements²⁶) of E and $4E\mp$ which are of the order of 12–13 and 11–12 kilocalories. This last is of the order of those of chemical reactions and hence the type of adsorption involved herein, is chemisorption²⁷). Evidence for (ii) has been obtained from the observation²⁹) that the effect of light investigated in various visible spectral regions is to cause two simultaneous changes, both instantaneous and light reversible: (a) a decrease in the amplitude of some of the h.f. pulses but (b) increase in their total number. An examination of a number of oscillograms²⁹) undertaken to obtain more information about (a) has revealed that the amplitude reduction on irradiation is apparently linked with alternate h.f. pulses, which is suggestive of the occurrence of $-di$. Now $-di$ would be reduced (numerically) due to the cooccurrence of (b), which *per se* should cause $+di$. The net influence of light under any given circumstances would therefore, depend on the resultant of (a) and (b) which alone is shown by the current detector.

4. When the applied electrical energy ($V > V_i$) exceeds the sum of the activation energy and heat of chemisorption, desorption²⁷) of the chemisorbed layer sets in, and as the electrical field is further increased, desorption increases. This decreases ϕ and hence photoelectron emission increases; applied field being very favourable for negative ion formation³⁰) ($X/p \neq 50$), $-di$ increases as shown by CD in Fig. 1. Evidence for this has been adduced from measurements²⁶) of E and $4E\mp$, for the adsorption process responsible for $-di$, which are of the order of 19–20 and 17–18 kilocalories. This is of the order of the sum E and $4E\mp$ for chemisorption²⁷), indicating thereby that desorption by the applied field of the chemisorbed layer is responsible for enhancement in $-di$ with V .

5. At very high applied electrical fields, negative ion formation decreases³⁰) ($X/p > 50 < 90$) and therefore $-di$ decreases as shown by DE in Fig. 1. At $X/p \geq 90$, $-di$, reverses to $+di$, due to detachment of electrons from negative ions³⁰), as has been observed at $V > V_i$ or $\geq V_m$ (EF in Fig. 1.)

6. It is further contemplated that the threshold potential V_m is characterised by the setting in of chemisorption; at this last, desorption of van der Waals' layer is maximum. Similarly at the inversion potentials V_i , the potential at which the observed $+di$ changes over to $-di$, desorption of the chemisorbed layer commences as also the formation of the chemisorbed layer is a maximum. It is therefore, likely that at constant mass conditions, there are two equilibrium processes (i)

between the formation and desorption of a chemisorbed layer and (ii) between a van der Waals' layer and a partially chemisorbed layer; variation in the energy (any form) supplied to the surface disturbs the equilibrium conditions.

It is instructive to note that the present mechanism attempts at an explanation on the basis of interaction between an adsorbed phase on an electrically excited surface and external radiation and is supported by the results on the activation energy measurements of such systems and was called for, to explain theoretical deficiencies in substantiating the potential variation of $\pm di$ and certain other experimental observations, which could not be explained otherwise. Work pertaining to a theoretical explanation of the results observed hitherto in the field of Joshi effect in the light of the above theory is being published elsewhere.

Grateful thanks of the author are due to Prof. S. S. Joshi for his valuable suggestions.

NMR Study of γ Ray Induced Polymerisation of Ethyl Acrylate

Toshikazu SHIBATA, Itsuro KIMURA
and Tokuo SUITA

*Department of Nuclear Engineering,
College of Engineering, Osaka
University, Osaka*

(Received September 15, 1958)

Some experimental results of proton magnetic resonance absorption of ethyl acrylate etc. during polymerisation are reported here.

The samples were prepared with sufficient purification and evacuation. The radiation source for γ ray irradiation was 100 curies of ^{60}Co and the dose rate was about 2×10^5 r/hr. The irradiation was carried out continuously except the occasional interruptions for observation of NMR. The Pound-Watkins circuit, lock-in amplifier and ordinary γ spectrometer techniques were used to observe the proton magnetic resonance. The magnetic field used was about 4500 gauss and its uniformity was some 10^{-2} gauss over the samples. Line width observed at lower doses was limited by the inhomogeneity of the magnetic field.

The resonance patterns varied with increasing γ ray doses. In the actual procedure, the second moment was taken for the line width, but the resonance curves in our case, were generally very narrow and submerged in the noises at the wings where the contribution to the second moment is large. Therefore, the line width obtained may have appreciable errors especially in lower dose region. In Fig. 1 the line width is plotted against

Fig. 1. Line width and maximum excursion curve against γ irradiated dose.

the γ irradiation dose in the case of ethyl acrylate.

In the same figure, the line intensity or conveniently the maximum excursion in its derivative curve is also shown as the dotted line.

The line intensity curve has a peak at a certain dose. Similar results were obtained on other monomers such as acrylonitril, methylmethacrylate etc., but their peaks occurred at different values of γ doses. It is interesting that the peaks of the line intensity curves occur at about the maximum slopes of the line width curves.

Following considerations may be given to the present result. The viscosity of samples increased with γ dose, because polymerisation occurred. The increase of viscosity shortens the spin lattice relaxation time T_1 as $T_1 \propto T/\eta$, where T is the temperature and η the viscosity of the samples.¹⁾ Hence the saturation effects are avoided at higher viscosity, and the line intensity or maximum excursion increases. The viscosity rises very rapidly even in the region before the D_{ex} peak, and the sample becomes apparently solid after only a few hours of irradiation. At the stage when the sample begun to solidify some hindered motions may still be possible. However, when the polymerisation is accomplished any internal motion characteristic to the liquid state may not be possible and accordingly D_{ex} decreases. Thus the peak occurs and simultaneously line width becomes larger.

More detailed experiments with other cooperative procedures on many other samples are now in progress.

The authors wish to thank Mr. H. Sumitomo for his help in the preparation of the samples.

Field Effect on Molybdenite

By Ichiro NAKADA

Kobayashi Institute of Physical Research,
Kokubunji, Tokyo

(Received September 10, 1958)

Previously the existence of the surface space charge layer on molybdenite was qualitatively assured by the measurement of surface conduction and surface photovoltaic effect¹⁾²⁾. Further quantitative investigation by the method of "field effect"³⁾ is reported.

The measurement is made on two kinds of surfaces; the one is prepared by the cleavage of a natural crystal and the other is the surface soaked in HCl or HNO₃ for a few seconds after cleaving. All the specimens measured are n-type with carrier

Fig. 1. Field effect of the freshly cleaved surface measured at 6.0°C.

Fig. 2. Field effect of the surface treated by HCl and measured at 3.8~3.9°C.

Fig. 3. The relation between the applied voltage and field effect obtained from the result of Fig. 2.

density of about $10^{16}/\text{cm}^3$. As the carrier density is a little too high for the performance of such experiments, the surface field up to $10^6\text{V}/\text{cm}$ is applied using a mica sheet as a separator. The highest field strength is limited by the electric breakdown of the mica sheet.

On the surface without any chemical treatment the field effect is as shown in Fig. 1. The relation between the applied field and the conductivity change is linear. From this linear relation only the level of the trapping state cannot be deduced anyway. Fig. 2 is the result on the chemically treated surface which would probably be covered with the electronegative gas layer of HCl. The relation between the applied voltage and the conductance change is shown in Fig. 3. In this case the notable trapping effect appears and from the nonlinearity of the field effect the behavior of the inversion layer can be analysed. With the assumption that the mobility of holes induced by the high negative field is reduced because of the narrow conducting path in the inversion layer⁴⁾, the result on the chemically treated surface is analysed as follows: the trapping level situates 1.4 eV below the conduction band and the state density is $4 \times 10^{12}/\text{cm}^2$ volt. The detail would be reported later.

Quadrupole Moment of the Second Excited State of ^{19}F

By Kenzo SUGIMOTO*, Akira MIZOBUCHI
and Hisasi YAMAMOTO

Department of Physics, Faculty of Science,
Osaka University, Osaka

(Received October 9, 1958)

Angular distributions of the 200-keV gamma-radiations by the reaction $^{19}\text{F}(p, p')^{19}\text{F}^*$ have been measured by bombarding a CaF_2 target and also a polytetrafluoroethylene $((\text{C}_2\text{F}_4)_n)$ target of each about 200-keV thickness for 1.4-MeV protons. Each distribution was fitted to the form $W(\theta)=1+A_2G_2P_2(\cos\theta)$, where A_2 is the coefficient of the distribution in the Legendre polynomial $P_2(\cos\theta)$, and predicted theoretically $0.40>A_2>0.143$ by Christy¹⁾, and G_2 is the attenuation factor caused by the effect of nuclear environment during the life $T_{1/2}=85\text{-m}\mu\text{sec}$ of the emitting state. $A_2G_2=0.242\pm0.010$ and $A_2G_2=0.071\pm0.010$ for the CaF_2 target and the polytetrafluoroethylene target were obtained respectively by 1.4-MeV incident protons. The result obtained by the CaF_2 target was in good agreement with the result obtained by Peterson, *et al.*²⁾, and if one assumes $0.6<G_2<0.8$ for this case following the discussion by Christy¹⁾, then one gets $G_2\sim0.2$ for the polytetrafluoroethylene target, which is just the hard core value of G_2 by the static quadrupole coupling of polycrystalline case³⁾.

The attenuation factor of the delayed correlation, $G_2(t)$, by the static quadrupole coupling of polycrystalline state was calculated by Abragam and Pound³⁾ as follows;

$$G_2(t)=\frac{1}{5}\left(1+\frac{13}{7}\cos\omega_0t+\frac{10}{7}\cos2\omega_0t+\frac{5}{7}\cos3\omega_0t\right), \quad (1)$$

for nuclear spin $I=5/2$, where

$$\omega_0=\frac{3}{2I(2I-1)}\frac{eQ(\partial^2V/\partial Z^2)}{\hbar} \quad (2)$$

is the angular frequency equivalent to the smallest nonvanishing energy difference by the pure quadrupole coupling with the field $\partial^2V/\partial Z^2$ of nuclear environment.

Delayed angular distribution were measured by using a chopped proton beam of 2-m μ sec duration and 100-m μ sec repetition rate, and employing a fast coincidence detector with NaI(Tl) scintillation spectrometer, whose resolving time was better than 10-m μ sec for 200-keV gamma-rays. Intensities of the radiations with various delayed times were measured for 0° and 90° with respect to the incident protons. The result of this delayed cor-

Fig. 1. Delayed angular distribution of the 200-keV radiations. The curves drawn in this figure were calculated theoretically for the respective frequency of the quadrupole coupling f_0^0 . The errors indicated are only statistical ones.

relation is shown in Fig. 1. The curves drawn in this figure were calculated with the formula (1) by considering the nuclear life time and geometrical factor of the experimental set-up, and assuming $A_2=0.35$. The result was only a preliminary one, but the delayed character was clearly seen, and the best fit with the case of the frequency $f_0^0=\omega_0/2\pi=7\text{ MC}$ of quadrupole coupling was obtained.

The C-F bonding energy of polytetrafluoroethylene is very high (120-kcal) and the examination under irradiation have shown that the main event caused by the radiation is a puncture of C-C bond⁴⁾. The recoil fluorine atom will travel many molecular layers losing its kinetic energy with ionization and in a relatively short period ($<10^{-10}$ sec) reach an energy comparable to the energy of C-F bond. One can assume that the recoil fluorine atom is trapped by the C-F bond of a polytetrafluoroethylene and the quadrupole field caused by the C-F bond effect to the excited nucleus.

Under this assumption, $\partial^2V/\partial Z^2$ can be calculated as $4.8\cdot10^{15}$ e.s.u. using the value q_{210} for the 2p electron by Barnes and Smith⁵⁾ and assuming the s-hybridization of 15% and the ionic character of 64% following the estimation by Towns⁶⁾. Inserting each values to the formula (2), the quadrupole moment of the excited state was obtained as

$$Q(^{19}\text{F}, \frac{5}{2}^+) \sim 0.13 \cdot 10^{-24} \text{ cm}^2.$$

J. PHYS. SOC. JAPAN **13** (1958) 1549**Ferroelectricity in the Phase III of KNO_3** By Shozo SAWADA, Shoichiro NOMURA
and Shin'ichi FUJII*Institute for Solid State Physics,
University of Tokyo*

(Received September 30, 1958)

Potassium nitrate (KNO_3) has the aragonite structure (D_{2h}^{16}) at room temperature (phase II). On heating, the crystal structure changes from orthorhombic to trigonal at about 130°C and the high temperature phase (phase I) is said to have the calcite structure (D_{3d}^{17}). On cooling, on the other hand, the phase I changes first to the phase III at about 124°C and next III to II at about 110°C ^{2),3)}. It has been reported that the temperature range corresponding to the phase III is broadened and III appears also on heating, by an application of high pressure^{4),5)} and that III belongs to the space group $C_{3v}^{6),5)}$.

We have found that the phase III is ferroelectric. Many of dielectric measurements have hitherto been made for fused samples, since the fact that crystals of KNO_3 are successively cracked by repeatedly passing through the 130°C transition^{6),7)} has let us hesitate to perform our measurements using only single crystals.

A disc electrode was suspended inside a cylindrical crucible which was used as another electrode and the diameter of disc electrode and the gap between two electrodes were 4 mm and 0.5 mm respectively. After being charged into the crucible, KNO_3 powder which had beforehand been dried in 10^{-3} mmHg vacuum at about 120°C for several days was melted in a furnace and slowly cooled down. Fig. 1 shows the $D \sim E$ hysteresis loop (max. field 17 kV/cm, 50 C/sec) at 121°C for a fused sample, from which the coercive field and the spontaneous polarization at this temperature turn out to be 4.5 kV/cm and $6.3 \mu\text{C}/\text{cm}^2$, respectively. The fact that the typical hysteresis loop is observed and the value of spontaneous polarization is large, even for the fused sample, would be noticeable.

Fig. 2 shows the permittivity *vs* temperature relation (1043 kC/sec) measured on heating and cooling for a twinned crystal (area 0.55 cm^2 , thickness 0.05 cm) using air-drying silver paste electrodes. In the phase I, the Curie-Weiss law holds with the Curie-Weiss temperature of 293°K and the Curie constant of $4.3 \times 10^5 \text{K}$.

The pyroelectricity was unambiguously observed in the phase III for fused samples. An effect of biasing field upon the permittivity-temperature relation was not clearly observed. The ferroelectricity in the phase III is considered to be due to a shift of the NO_3 group in the *c*-direction from

Fig. 1. Hysteresis loop at 121°C .Fig. 2. Permittivity (1043 kC/sec) *vs* temperature for a twinned crystal.

the center of a rhombohedral unit cell whose corners are occupied by K ions. The result that the phase III is ferroelectric may lead us to imagine that the phase II is antiferroelectric in the *b*-direction, since the aragonite structure is antipolar in this direction, but no double hysteresis loop was observed just below the III $\rightarrow$ II transition at least for fused samples. The fact that no bias effect and no double hysteresis loop were observed might partly be due to large amounts of latent heat at I $\rightarrow$ III and III $\rightarrow$ II transitions^{3),8)}.

Although the change of twin structure of crystals at each transition could be observed under a polarized light microscope, these twins would not be ferroelectric domains. More thorough studies on single crystals will be shortly reported.

J. PHYS. SOC. JAPAN **13** (1958) 1550~1551**Thermal Conductivity of BaTiO₃ Ceramics**By Ikushi YOSHIDA, Shoichiro NOMURA
and Shozo SAWADA*Institute for Solid State Physics,
University of Tokyo*

(Received September 30, 1958)

A great deal of investigations of the thermal conductivity of insulators, performed by many workers¹⁾, have made it clear that the temperature dependence of the thermal conductivity of simple, insulating crystals can be explained, at least qualitatively, by the phonon theory²⁾. The status of understanding in cases of more complex crystals, however, remains very unsatisfactory. The behavior of thermal conductivity of crystals with phase transformations has been thought to be beyond our grasp, although some contributions have been reported concerning molecular crystals³⁾.

Many properties of ferroelectric and antiferroelectric substances have been investigated, but the measurement of thermal conductivity has scarcely been made⁴⁾, although by this measurement there seems a reasonable promise for shedding some light on the understanding of the above problems.

We have planned to investigate the temperature dependence of thermal conductivity of a series of substances including ferroelectrics, antiferroelectrics and their solid solutions, with hopes to get some knowledge on, how the phonons are scattered by ferroelectric domain boundaries, or how they are coupled together in the ferroelectric and antiferroelectric state, or what the situation is, compared with molecular crystals reported formerly.

The specimens used were sintered from BaCO₃ and TiO₂ powders of the special reagent grade by the usual method. The thermal conductivity of the specimen was compared with that of pure iron by a so-called "divided bar method".

Fig. 1 shows the temperature dependence of the thermal conductivity of BaTiO₃ ceramics. Its absolute value at 100°C is about 28 mW/cm.deg., which is rather high for such a ceramic substance. The temperature coefficient is negative, but it does not obey the 1/T law required by the phonon theory. Most noticeable is the small hump at about 120°C, which is the ferro-para transition temperature. For comparison, the thermal conductivity of SrTiO₃ ceramics measured in the same temperature range is shown in Fig. 2. This substance belongs, as is well known, to the perovskite group as BaTiO₃ does, but is not ferroelectric. In this case, the temperature coefficient was also negative but no anomaly was observed. The absolute value at 100°C is about 52 mW/cm.deg., nearly twice that of BaTiO₃. A preliminary measurement for ferroelectric PbTiO₃, which has also the same crystal

Fig. 1. Thermal conductivity of BaTiO₃ ceramics.Fig. 2. Thermal conductivity of SrTiO₃ ceramics.

structure, has been performed. As far as the present stage of the measurement tells us, a similar tendency as in the case of BaTiO₃ is observed. The value at 100°C is about 29 mW/cm.deg., which is also comparable to that of BaTiO₃.

Of the three specimens that we have measured, only SrTiO₃ showed the conspicuously high value of thermal conductivity. Porosity of these ceramic specimens might prohibit such a direct comparison of the absolute values, but all of our specimens have nearly equal porosity slightly larger than 10%, and, as has been reported⁵⁾, the effect of not extremely large porosity would safely be eliminated by using a simple formula. After all, the fact that SrTiO₃ is thermally much more conductive than BaTiO₃ or PbTiO₃ would not be a mere result of the difference of porosities. Then, we infer, this fact seems to suggest an intimate relation of the thermal conductivity with the ferroelectricity, resulting from a singular behavior of the thermal vibration of ions shifted to cause the ferroelectricity.

Investigations of other perovskite crystals, their solid solutions and other classes of ferroelectric substances in a wider temperature range are now in progress.

Difference between Dynamic and Static Surface Tensions*

By Sohei KONDO

National Institute of Genetics, Misima, Japan

(Received January 21, 1958)

We consider a plane non-equilibrium interface between phases α and β . Following Defay¹⁾, we consider the system as composed of many thin, substantially homogeneous layers $-u, \dots, 0, 1, \dots, w$, with thickness d , each being parallel to the interface. Let p_T^t denote the tangential pressure of the t -th layer; p^α and p^β the pressures of bulk phases α and β . The mechanical definition of surface tension γ , which is applicable to non-equilibrium interfaces as well, gives²⁾

$$\gamma = d \sum_{t=-u}^w (p^{\alpha\beta} - p_T^t), \quad (1)$$

$$p^\alpha = p^\alpha(1 - A(t)) + p^\beta A(t); \quad A(t) = \begin{cases} 0, & t < 0 \\ 1, & t \geq 0 \end{cases} \quad (2)$$

where Gibbs' dividing surface is placed between the layers 0 and 1. We can get a non-equilibrium interface called the "completely fresh surface", where the concentration is the same as in the interior of the bulk liquid phase, by bringing rapidly an amount of the interior part to an equilibrium interface, keeping the composition unaltered^{3,4)}. The completely fresh surface, when left in a natural aging process, will tend to equilibrium passing through various, intermediately fresh states. Surface tension of such a fresh surface is called "dynamic surface tension" and that of an equilibrium interface "static surface tension"^{3,4)}. For simplicity, we assume in the following treatment that liquid phase α is confined below the layer 0 while vapor phase β can be treated as a vacuum.

We suppose an alternative way to obtain a fresh surface of a pure liquid, whose density is larger than that of the corresponding equilibrium interface. We can change the equilibrium interface into the desired fresh interface by giving rapidly some proper amounts of tangential isothermal contraction to layers 1, 2, $\dots$, respectively. This will cause increases of $p_T^1, p_T^2, \dots$, if each layer obeys a relation similar to the equation of state of liquids^{5,6)}. Thus, the fresh interface has tangential

pressures higher than those of the equilibrium interface. Then, from (1) we may conclude that dynamic surface tension of a pure liquid is smaller than static one. According to Harasima's⁵⁾ calculation based on Kirkwood and Buff's⁶⁾ statistical-mechanical treatment of surface tension of liquid argon at 90°K, p_T^t becomes highly positive in the completely fresh interface. This means from (1) that the pure dynamic surface tension (surface tension of a completely fresh surface) of liquid argon is highly negative and much less than the static surface tension of 11.9 dyne/cm⁷⁾. We find in a similar manner that surface tension of a non-equilibrium interface, where the density transition from liquid to vapor is less sharp than in the equilibrium interface, is larger than the static surface tension.

Now we consider a dilute solution with a plane interface, in which the solvent is in equilibrium while the solutes are out of equilibrium. If the adsorption is positive, a fresh surface must have a lower concentration than that of the equilibrium interface. The fresh surface can be brought about by diluting rapidly at constant temperature the solution in the equilibrium interface until the latter gains the same concentration as the desired fresh surface. To carry out this dilution procedure, we assume that one of the walls of the container is composed of stripped semi-permeable membranes of width d , which are permeable only to the solvent and in contact with a pure liquid in an osmotic equilibrium with the above solution. Then, we can change the concentration of any layer into the desired one by pushing outward rapidly the strip membrane of the layer. This procedure will decrease $p_T^1, p_T^2, \dots$. We then find from (1) that for the case of positive adsorption, dynamic surface tension must be larger than static one. This agrees with experimental results⁷⁾. Similarly, we find that for negative adsorption, dynamic surface tension will be smaller than static one. This is expected to be observed in the case of ionic solutions. The details of the present treatment based on quasi-thermodynamics³⁾ and statistical mechanics will be presented elsewhere. This work is partly supported by grant-in-aid for scientific research from the Ministry of Education.

No. 6

Gamma Rays from the Proton Bombardment of Silicon.		
..... Eiji OKADA, Iwao MIURA, Tetsuo WAKATSUKI and Yasuo HIRAO		541
Magnetic Spectrometer having Inclined Plane Pole-Faces for Low-energy Electrons.		
.....	Susumu KATO	544

On the Magnetic Annealing Effect in 2% Cobalt-Copper Alloy-I. Induced Ferromagnetic Anisotropy.....	Tadayasu MITUI	549
Electrical and Optical Properties of GeS.	Tadaichi YABUMOTO	559
Electronic Structure and Diamagnetism of Graphite.	Shoichi MASE	563
Electron Spin Resonance of Z_1 -centers in Potassium Chloride.	Hazimu KAWAMURA and Keiko ISHIWATARI	574
Magnetic Anisotropy Measurements of NiO Single Crystal.....	Hisamoto KONDOH, Enji UCHIDA, Yoshihide NAKAZUMI and Takeo NAGAMIYA	579
Fine Structures of X-ray K Absorption Spectra of Nickel in Oxides of Nickel.	Kenjiro TSUTSUMI	586
Fine Structures of the X-ray Absorption by the Single Crystals of Germanium.....	Kenjiro TSUTSUMI and Masayoshi OBASHI	591
Nuclear Magnetic Resonance Experiment on Metal Cadmium. II....	Yoshika MASUDA	597
Effects of Ionizing Radiations on Polyethylene.....	Kenichi SHINOHARA, Ayao AMEMIYA and Akibumi DANNO	604
Effects of Ionizing Radiations on Polyvinyl Alcohol-I. Breakdown of Main-chain and Formation of Carbonyl Groups.	Akibumi DANNO	609
Effects of Ionizing Radiation on Polyvinyl Alcohol II. Changes of Physical Properties of the Irradiated Specimen Caused by Heat Treatment.	Akibumi DANNO	614
Nuclear Quadrupole Resonances in Arsenic and Antimony Trihalides and Sulphur Molecular Addition Compounds.....	Shizuko OGAWA	618
A Torsion Magnetometer for Determining Free Radicals in Some Organic Solutions	Hideo TAKAKI, Naoto KAWAI, Chie MIYAKE and Tadasuke MORITA	629
On the Flow of a Viscous Fluid past a thin Screen at Small Reynolds Numbers...	Hidegori HASHIMOTO	633
Asymptotic Behaviour of the Response Function of an Optical System with the Primary Spherical Aberration.	Hiroshi ITÔ	639
Adsorption of Water Vapour on Glass and Other Materials in Vacuum.	Hiroaki OKAMOTO and Yutaka TUZI	649

SHORT NOTES

Specific Heats of Copper Ferrite.....	Thoru INOUE and Shuichi IIDA	656
The Q -value for the $N^{14}(n, \alpha)B^{11}$ Reaction.	Tadayoshi DOKE, Shoji SUZUKI and Iwao OGAWA	656
A Richter Type Magnetic Loss in Yttrium-Iron Garnet.	Hisashi SEKIZAWA, Shûichi IIDA and Tomonao MIYADAI	658
On the Measurement of Isotope Abundance of Lithium with Mass Spectrometer....	Itiro OMURA and Nozomu MORITA	659
Higher Order Transitions in Double Nuclear Resonance Experiments in Solids.	N. BLOEMBERGEN	660
Polarization Reversal in Triglycine Sulphate Crystal.	Kiyasu ZENITI, Kazuo HUSHIMI and Keisuke KATAOKA	661

Errata

The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent Metals.....	Mikio TSUJI	655
Structural Investigation by Means of Nuclear Quadrupole Resonance II.	Kenji SHIMOMURA	655

No. 7

Isotope Shift in the Spectrum of WI....	John A. VREELAND and Kiyoshi MURAKAWA	663
On the Electrical Properties of Polycrystalline Boron.....	Ryosei UNO	667
Change of Oxygen Concentration with Temperature of the Nickel and Cobalt Oxide Solid Solutions.	Tamio SAKATA and Kimiko SAKATA	675
Paramagnetic Effect in Superconductors. Part I. Quasi-Paramagnetism and Resistance of Indium at the Superconducting Transition.....	Yoshio SHIBUYA	684
Paramagnetic Effect in Superconductors. Part II. Quasi-Paramagnetism in Non-Circular Cylindrical Tin Specimens.	Yoshio SHIBUYA	695

The Effect of Tension on the Magnetostriction of Iron Single Crystals.	703
..... Hideo TAKAKI and Jun-ichi HAYASHI	
Electronmicroscopic Observation of Coloured and Bleached Alkali- Halide Crystals.	709
..... Tadatosi HIBI and Kazuo ISHIKAWA	
A Note on Thermodynamics of the Harmonic Oscillator with Radiation Damping.	717
..... Nobuhiko SAITÔ and Jun-ichi HORI	
Gel Formation of Aqueous Solution of Polyvinyl Alcohol Irradiated by Gamma	
Rays from Cobalt-60.....Akibumi DANNO	722
The Paramagnetic Resonance Absorption of Some Free Radicals in Sulfuric Acid	
Solution. Yasaburo YOKOZAWA	727
Moving Striations in Arc Discharge.....	
.....Hirosi YOSIMOTO, Mituo SATO and Yasuhiro NAKAO	734
Moving Striations due to Space Charge Waves.....	
.....Hirosi YOSIMOTO, Mituo SATO and Yasuhiro NAKAO	741
Flow Formation with Suction or Injection. R. S. NANDA	748

SHORT NOTES

The Magnetic Field at the Nucleus of Sm^{++} induced by Paramagnetism of 4f-	
Electrons. Junjiro KANAMORI and Kenzo SUGIMOTO	754
Plasma Oscillation in the Electrically Conductive Tin Oxide Film.	
..... Kozo ISHIGURO, Taizô SASAKI, Toshihiro ARAI and Isamu IMAI	755
Magnetic annealing of Fe_3Al Single Crystal. Kenzô SUZUKI	756
Magnetic Properties of Nickel and Cobalt Ferrite-Chromite Series	
..... Syohei MIYAHARA and Tachiro TSUSHIMA	758
On Magneto-Acoustic Resonance in Metals. Nobuo MIKOSHIBA	759
Space Charge Phenomena in Nitrobenzene under High Electric Field.....	
..... Pyong-un CHONG, Chiyoe YAMANAKA and Tokuo SUITA	760
Electric Breakdown and Conduction in BaTiO_3 Single Crystals.....	
..... Yoshio INUISHI and Shigeyuki UEMATSU	761
Diffusion of Iron in Single Crystals of Copper....Yuzo TOMONO and Akira IKUSHIMA	762
Beta and Gamma Ray Spectroscopy of Co^{60}	
..... Kazumasa KAMADA, Tomoyuki TERANISHI and Yasukazu YOSHIKAWA	763
A Note on Direct Observation of Dislocations by Electron Microscopy.....	
..... Hatsujiro HASHIMOTO and Toshio NAIKI	764
On the Auger Ejection of Electrons from Nickel by Inert Gas Ions.	
..... Yoshiyuki TAKEISHI	766
A Note on the Normal Cathode Fall in the Glow Discharges in Inert Gases.	
..... Yoshiyuki TAKEISHI	767
Electron Spin Resonance of Eu^{++} in Natural CaF_2	
..... On MATUMURA, Kazumi HÔRAI and Zen'emon MIDUNO	768
Measurement of the Thermal Conductivity in Semiconductors. Riro NII	769

No. 8

Elastic and Inelastic Scattering of Protons from Neon	
..... Michiya KONDO and Takashi YAMAZAKI	771
Angular Distribution of Protons Inelastically Scattered from Si^{28} and Mg^{24}	
.... Shotaro YAMABE, Michiya KONDO, Takashi YAMAZAKI and Atsutomo TOI	777
An Experimental Study of Extensive Air Showers.	
Saburo MIYAKE, Kensaku HINOTANI, Tatsunosuke KANEKO and Itsuo KATSUMATA	782
Recombination Centers in Germanium.....Jun'ichi OKADA	793
One to One Correspondence between Etch Pits and Dislocations in KCl Crystals..	
..... Masayoshi SAKAMOTO and Shunsuke KOBAYASHI	800
The Internal Friction of Barium Titanate Ceramics. Takuro IKEDA	809
The Thermoelectric, Galvanomagnetic and Thermomagnètic Effects of Monovalent	
Metals. II. The Thermoelectric Power for Anisotropic Media...Mikio TSUJI	818
An Order-Disorder Transformation Phenomenon in the $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ Solid Solution	
Series.....Yoshikazu ISHIKAWA	828

Diffusion of Cadmium into Single Crystals of Copper.	
Tokutaro HIRONE, Nobuhiko KUNITOMI, Masanobu SAKAMOTO and Hideo YAMAKI	838
Diffusion of Cobalt into Iron-Cobalt Alloy.....	
..... Tokutaro HIRONE, Nobuhiko KUNITOMI and Masanobu SAKAMOTO	840
Diffusion of Cobalt into Single Crystals of Copper.....	Masanobu SAKAMOTO 845
The Theory of the Fine Structure of the X-ray Absorption Spectrum.	
..... Toshio SHIRAIWA, Tsutomu ISHIMURA and Masao SAWADA	847
Nuclear Quadrupole Spectra of Boron Trichloride and Tribromide....	Takehiko CHIBA 860
Zeeman Effect of Nuclear Quadrupole Resonance Spectrum in Cyanuryl Chloride...	
.. Yonezo MORINO, Takehiko CHIBA, Takashi SHIMOZAWA and Masaharu TOYAMA	869
Absorption Spectra of Cr^{3+} in Al_2O_3 . Part A. Theoretical Studies of the Absorp-	
tion Bands and Lines.....	Satoru SUGANO and Yukito TANABE 880
Absorption Spectra of Cr^{3+} in Al_2O_3 . Part B. Experimental Studies of the Zeeman	
Effect and other Properties of the Line Spectra.....	
..... Satoru SUGANO and Ikuji TSUJIKAWA	899
Measurements of Free Induction Decay Time and Spin-Lattice Relaxation Time of	
Bromine Nucleus in Sodium Bromate	Tsuneo HASHI 911
Zeeman Study on Nuclear Quadrupole Resonances in AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$...	Yoshihito ABE 918
Elementary Problems on the Configurations of a Linear High Polymer...Kazuo NAGAI	928
An Application of the Cellular Method to a Vacancy in Metal.	Hiroshi FUJIWARA 935
Characteristics of the Beam Type Maser. II.	Koichi SHIMODA 939
The Maximum Disturbance Growth Rate for an Unstable Plasma Column.	
..... Shobu KANEKO	947
Note on the Forces on an Elliptic Cylinder moving in a Viscous Liquid at Small	
Reynolds Numbers.....	Yorisaburo TAKAISI 954
Adsorption of Water Vapour on Lead Borosilicate Glass in Vacuum.....	
..... Yutaka TUZI and Hiroaki OKAMOTO	960

SHORT NOTES

Variation of the Optical Properties of Iron at Transition Temperature...Akira KINBARA	966
Electrical Conductivity in N-type InSb under Strong Electric Field. Yasuo KANAI	967
Low Temperature Anomaly in the Proton Resonance of Some Nickel Salts.....	
..... Pil Hyon KIM and Tadashi SUGAWARA	968
A New Compound in Au-Pb Alloy System.	
..... Yoshibumi FUJIKI, Ryōji SUGANUMA and Toshiho YOSHIDA	969
Etch Pits in Lead Crystals.	Yosio HIKI 970
Paramagnetic Resonance Spectrum of Manganese in Single Crystals of Alkali Halide	
Grown from the Melt.	
..... Kuniya FUKUDA, Yoichi UCHIDA and Hisamitsu YOSHIMURA	971
Some Electrical and Optical Properties of Tin Monosulphide. Tadaichi YABUMOTO	972

Errata

The Q-value for the $\text{N}^{14}(n, \alpha)\text{B}^{11}$ Reaction.	
..... Tadayoshi DOKE, Shoji SUZUKI and Iwao OGAWA	973

No. 9

Dipolar Broadening of the Quadrupole Resonance Lines in Crystals NaClO_3 , NaBrO_3	
..... Kenji KANŌ	975
The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent	
Metals. III. The Galvanomagnetic and Thermomagnetic Effects for An-	
isotropic Media.	Mikio TSUJI 979
Paramagnetic Resonance in Copper Propionate Monohydrate.....	Hidetaro ABE 987
Variation of Hall Coefficient of Some Non-ferromagnetic Superlattice Alloys.	
..... Kiyoshi YONEMITSU and Takao SATO	998
Study of Metallic Carbides by Electron Diffraction. Part II. Crystal Structure	
Analysis of Nickel Carbide.	Sigemaro NAGAKURA 1005

Electron Diffraction Study of Evaporated Face-centered Cubic Crystallites.	Hidetake MORIMOTO 1015
The Electron Distribution and the Location of the Bonded Hydrogen Atom in Crystals.....	Yujiro TOMIIE 1030
Luminescence and Dichroism of <i>F'</i> and <i>M</i> Centers in Potassium Chloride.....	Goro KUWABARA and Akira MISU 1038
The Flow with Wake past an Oblique Plate	Yōichi MIMURA 1048
Flow past a Bent Flat Plate with an Unsymmetric Dead Air at Mach Number 1...	Takeo SAKURAI 1055

SHORT NOTES

Observation of the Lateral Photovoltage by Surface Field Effect.	Makoto KIKUCHI 1061
Study on Annealing of Radiation Induced $1/f$ Noise in Ge <i>p-n</i> Junction.	Ki-ichi KOMATSUBARA and Utaka HASHIMOTO 1062
A Remark on the Chemical Kinetics in Polymers during Irradiation.	Tsutomu WATANABE 1063
Effects of Impurities and Temperature on the Spectra of Electroluminescence.	Ryoichiro HUZIMURA and Tunahiko SIDEI 1064
Electrical Conductivity in <i>p</i> -Type InSb Under Strong Electric Field.	Yasuo KANAI 1065
Piezo-Effect of Selenium Rectifiers.	Tadasi NUMATA 1066
Structure of the <i>F'</i> Band in Potassium Chloride.	Goro KUWABARA and Akira MISU 1066
Small Angle Scattering of X-rays by Deuteron-irradiated Germanium Crystal.	Francisco Eiichi FUJITA and Ulrich GONSER 1068
A Note on Numerical Evaluation of Integral Square Error.....	Sitiro MINAGAWA 1069

Errata

A Note on the Normal Cathode Fall in the Glow Discharges in Inert Gases.	Yoshiyuki TAKEISHI 1070
---	-------------------------

No. 10

Excited States of Pt^{192}	Mitsuhiro KAWAMURA, Atsushi AOKI and Takeo HAYASHI 1071
Sector Type Double Focusing Beta Ray Spectrometer. Part I. General Properties	Mitsuo SAKAI and Hidetsugu IKEGAMI 1076
Sector Type Double Focusing Beta Ray Spectrometer. Part II. Twin Setting Measurement of the Weak Higher Component of Cs^{137}	Toshimitsu YAMAZAKI, Hidetsugu IKEGAMI and Mitsuo SAKAI 1080
Temperature Distribution during the Martensite Plate Formation.	Zenji NISHIYAMA, Akira TSUBAKI, Hideo SUZUKI and Yasusada YAMADA 1084
Theory of Thermoelectric Power of Ionic Crystals (I).....	Eijirō HAGA 1090
A Theory of Impurity Conduction. I.	Tadao KASUYA 1096
Magnetic Property and Crystal Chemistry of Ilmenite ($MeTiO_3$) and Hematite (αFe_2O_3) System. I. Crystal Chemistry.	Yoshikazu ISHIKAWA and Syun-iti AKIMOTO 1110
Lattice Defects in Zincblende. Part I. Phenomenological Expressions of Interionic Potentials.....	Sumitada ASANO and Yasuo TOMISHIMA 1119
Lattice Defects in Zincblende. Part II. Formation Energy of Lattice Defects.	Sumitada ASANO and Yasuo TOMISHIMA 1126
Internal Friction of Lead. I.	Yosio HIKI 1138
Scattering of Electrons by Carbon Films.	Yoshihiro KAMIYA 1144
The Crystal Structure of Germanium Selenide $GeSe$	Atsushi OKAZAKI 1151
Anisotropy of Nuclear Magnetic Resonance due to Crystal Dislocations...Eizo OTSUKA 1155	
Effect of Velocity Gradient on the Radial Distribution of Polymer Molecules in Dilute Solution.....	Ryuzo KOYAMA 1167
Paramagnetic Resonance Spectrum of Mn^{++} in NaCl Single Crystal.	Kazuo MORIGAKI, Minoru FUJIMOTO and Junkichi ITOH 1174
Nuclear Magnetic Resonance Studies of Iodine Ions in Aqueous Solution.....	Junkichi ITOH and Yukio YAMAGATA 1182

The Lower Excited States and the Phosphorescent State of Diphenyl. II. Scheme of Modification of MO.	Kaoru IGUCHI	1186
Methods of Approximation of Molecular Integrals. I.	Sigeru HUZINAGA	1189
The Visco-elastic Properties of Network Structure. III. Normal Stress Effect (Weissenberg Effect).	Misazo YAMAMOTO	1200
Disturbance Phenomena in Probe Measurement of Ionized Gases.	Takayoshi OKUDA and Kenzo YAMAMOTO	1212
Magneto-hydrodynamic Oscillations of a Perfectly Conducting Fluid Sphere Placed in a Uniform Magnetic Field.	Tsuneji RIKITAKE	1224

SHORT NOTES

Chemical and Thermal Polish of KCl Crystals.	Masayoshi SAKAMOTO and Shunsuke KOBAYASHI	1231
Nuclear Magnetic Resonance Experiments of I^{127} in KI.	Junkichi ITOH and Yukio YAMAGATA	1232
A Proposed Explanation of Irradiation Growth of Uranium.	Ryukiti R. HASIGUTI, Hideo SAKAIRI and Tetuya SUGAI	1233
On the Conduction Mechanism of Oxide Coated Cathode.	Hiroyuki MIZUNO	1234
The Far Infrared Absorption of Sulfides, Selenides and Tellurides of Zinc and Cadmium.	Akiyoshi MITSUISHI, Hiroshi YOSHINAGA and Shigeru FUJITA	1235
The Far Infrared Absorption of Ferrites.	Akiyoshi MITSUISHI, Hiroshi YOSHINAGA and Shigeru FUJITA	1236
Growth and Extinction of Guanidine Aluminum Sulfate Hexahydrate Crystals.	Atsuo NISHIOKA and Kyoza SEKIKAWA	1237

Errata

The Electron Distribution and the Location of Bonded Hydrogen Atom in Crystals.	Yujiro TOMIE	1239
Diffusion of Cobalt into Single Crystals of Copper.	Masanobu SAKAMOTO	1239
Piezo-Effect of Selenium Rectifiers.	Tadasi NUMATA	1239

No. 11

The Reaction $F^{19}(d, n)Ne^{20}$ and the Energy Levels of Ne^{20}	Susumu MORITA and Kenji TAKESHITA	1241
Differential Elastic Scattering of 14 MeV Neutrons in Aluminum, Iron, Lead and Bismuth for Large Angles.	Kazunori YUASA	1248
The Multiplicity of Mesons Produced in the Nuclear Interaction of High Energy Nucleons and α -Particles in Cosmic Radiation.	Shin-ichi KANEKO	1258
On the Theory of the Brownian Motion.	Morikazu TODA	1266
Excess Noise in Narrow Germanium p - n Junctions.	Tatsuo YAJIMA and Leo ESAKI	1281
A Theory of Impurity Conduction. II.	Tadao KASUYA and Sigenao KOIDE	1287
Magnetic Property and Crystal Chemistry of Ilmenite ($MeTiO_3$) and Hematite (αFe_2O_3) System II. Magnetic Property.	Yoshikazu ISHIKAWA and Syun-iti AKIMOTO	1298
The Temperature Dependence of Forced Magnetostriction.	Toshiro TSUJI	1310
Diffusion Processes in Polymers under Irradiation; Polyvinyl Alcohol and CCl_4 System.	Tsutomu WATANABE	1316
The Study of the Transition Phenomena of Chain Polymers by the Photoelastic Method.	Motozo KANEKO	1324
Paramagnetic Relaxation of Copper Tutton Salt.	Yosuke NAGAOKA	1328
Spin Quenching and Magnetic Resonance.	Tôru MORIYA and Yukio OBATA	1333
Nuclear Magnetic Resonance of Transition Elements in Paramagnetic Salts.	Tôru MORIYA	1344
Electroluminescence of Insulated Particles.	Keiji MAEDA	1352
Phenomenological Free Streamline Theory, Part 1. Flow past a Normal Plate.	Yôichi MIMURA	1361
On the Acoustic Field by a Vibrating Source Arbitrarily Distributed on a Ribbon Plate. I.	Norio KAWAI	1374

A New Approach to the Theory of Slender Body in Compressible Flow.	Haruo MORIGUCHI 1384
Attenuation of Ultrasonic Waves in Suspensions of Viscoelastic Spheres.	Yasaku WADA 1390
On the Limit of Superheat.	Hiromu WAKESHIMA and Kazuo TAKATA 1398

SHORT NOTES

Etch Pits of Sb Single Crystals.	Jiro SHIGETA and Makoto HIRAMATSU 1404
Molecular Collisions in the Two-Dimensional Gases.	Kazuo TAKAYANAGI 1405
A Note on the Magnetoresistance Effect of Strain Gauge Wire.	Hideo TAKAKI and Toshiro TSUJI 1406
A Certain Anomalous Behavior of Iron Sulfides.	Miyuki MURAKAMI and Eiji HIRAHARA 1407
On the Mechanical Loss of Polyethylene.	Yasaku WADA 1408
Study on the Correlation between the Noise by Hole Generation and Surface Re-combination Velocity at Ge Fused Junction.	Kiichi KOMATSUBARA 1409
On RF Electrodeless Discharges in a Capillary. ..	Shigeo TAKEMOTO and Mineo KASAI 1410
Dichroism of Color Centers in KCl Crystal.	Takehiko ISHII, Tetsuhiko TOMIKI and Masayasu UETA 1411

Errata

Crystal Structure and Phase Transition of Some Metallic Halides (IV). On the Anomalous Structure of α -Ag I.	Sadao HOSHINO 1412
Adsorption of Water Vapour on Glass and Other Materials in Vacuum.	Hiroaki OKAMOTO and Yutaka TUZI 1412
Adsorption of Water Vapour on Lead Borosilicate Glass in Vacuum.	Yutaka TUZI and Hiroaki OKAMOTO 1412

No. 12

On the Observation of Magnetic Poles.	Eiichi GOTO 1413
Gamma Ray Spectroscopy of Mn ⁶⁴	Tosio KATO, Masao NOZAWA, Yasukazu YOSHIZAWA and Yujiro KOH 1419
Grain Boundary-Hardening due to Piled-up Dislocations.	Jin-ichi TAKAMURA and Sei MIURA 1421
On the V-centers in KBr Crystals.	Yoshio NAKAI 1424
On the Magnetic Properties of Nickel Sulfide.	Ichiro TSUBOKAWA 1432
Relaxation Spectrum of Chain High Polymeric Substances.	Tsuyoshi ONISHI and Misazo YAMAMOTO 1439
On the Ferromagnetic Phase in Manganese-Aluminum System.	Hiroshi KÖNO 1444
Effects of High Energy Radiation on Polymers II. End-linking and Gel Fraction.	Osamu SAITO 1451
Effects of High Energy Radiation on Polymers III. Viscosity.	Osamu SAITO 1465
Theory of Excited Plasma Waves.	Masao SUMI 1476
Half-Shadow Device for the Precise Measurement of the Principle Angle of Incidence.	Koreo KINOSITA and Sadao NOMURA 1485
On the Theory of Fluids.	Kazuo HIROIKE 1497
Effect of Transverse Magnetic Field on the Flow due to an Oscillating Flat Plate.	Tsunehiko KAKUTANI 1504
Some Nonlinear Effect in Compressible Flow.	Haruo MORIGUCHI 1510
The Forces Experienced by a Lattice of Equal Flat Plates in a Uniform Flow at Small Reynolds Numbers.	Shinji KUWABARA 1516
Deviation from Linearity of the Concentration Dependence of the Molecular Sound Velocity in Liquid Mixtures.	Otohiko NOMOTO 1524
Empirical Formula for Sound Velocity in Liquid Mixtures.	Otohiko NOMOTO 1528
Condenser Microphones with Plastic Diaphragms for Airborne Ultrasonics, I.	Kiichiro MATSUZAWA 1533

SHORT NOTES

A Possible Mechanism of the Potential Variation of Joshi Effect.	M. VENUGOPALAN	1544
NMR Study of γ Ray Induced Polymerisation of Ethyl Acrylate.....		
.....	Toshikazu SHIBATA, Itsuro KIMURA and Tokuo SUITA	1546
Field Effect on Molybdenite.....	Ichiro NAKADA	1547
Quadrupole Moment of the Second Excited State of ^{19}F		
.....	Kenzo SUGIMOTO, Akira MIZOBUCHI and Hisasi YAMAMOTO	1548
Ferroelectricity in the Phase III of KNO_3		
.....	Shozo SAWADA, Shoichiro NOMURA and Shin'ichi FUJII	1549
Thermal Conductivity of BaTiO_3 Ceramics.		
.....	Ikushi YOSHIDA, Shoichiro NOMURA and Shozo SAWADA	1550
Difference between Dynamic and Static Surface Tensions.	Sohei KONDO	1551

Erratum

Temperature Distribution during the Martensite Plate Formation.....		
....	Zenji NISHIYAMA, Akira TSUBAKI, Hideo SUZUKI and Yasusada YAMADA	1543
